

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

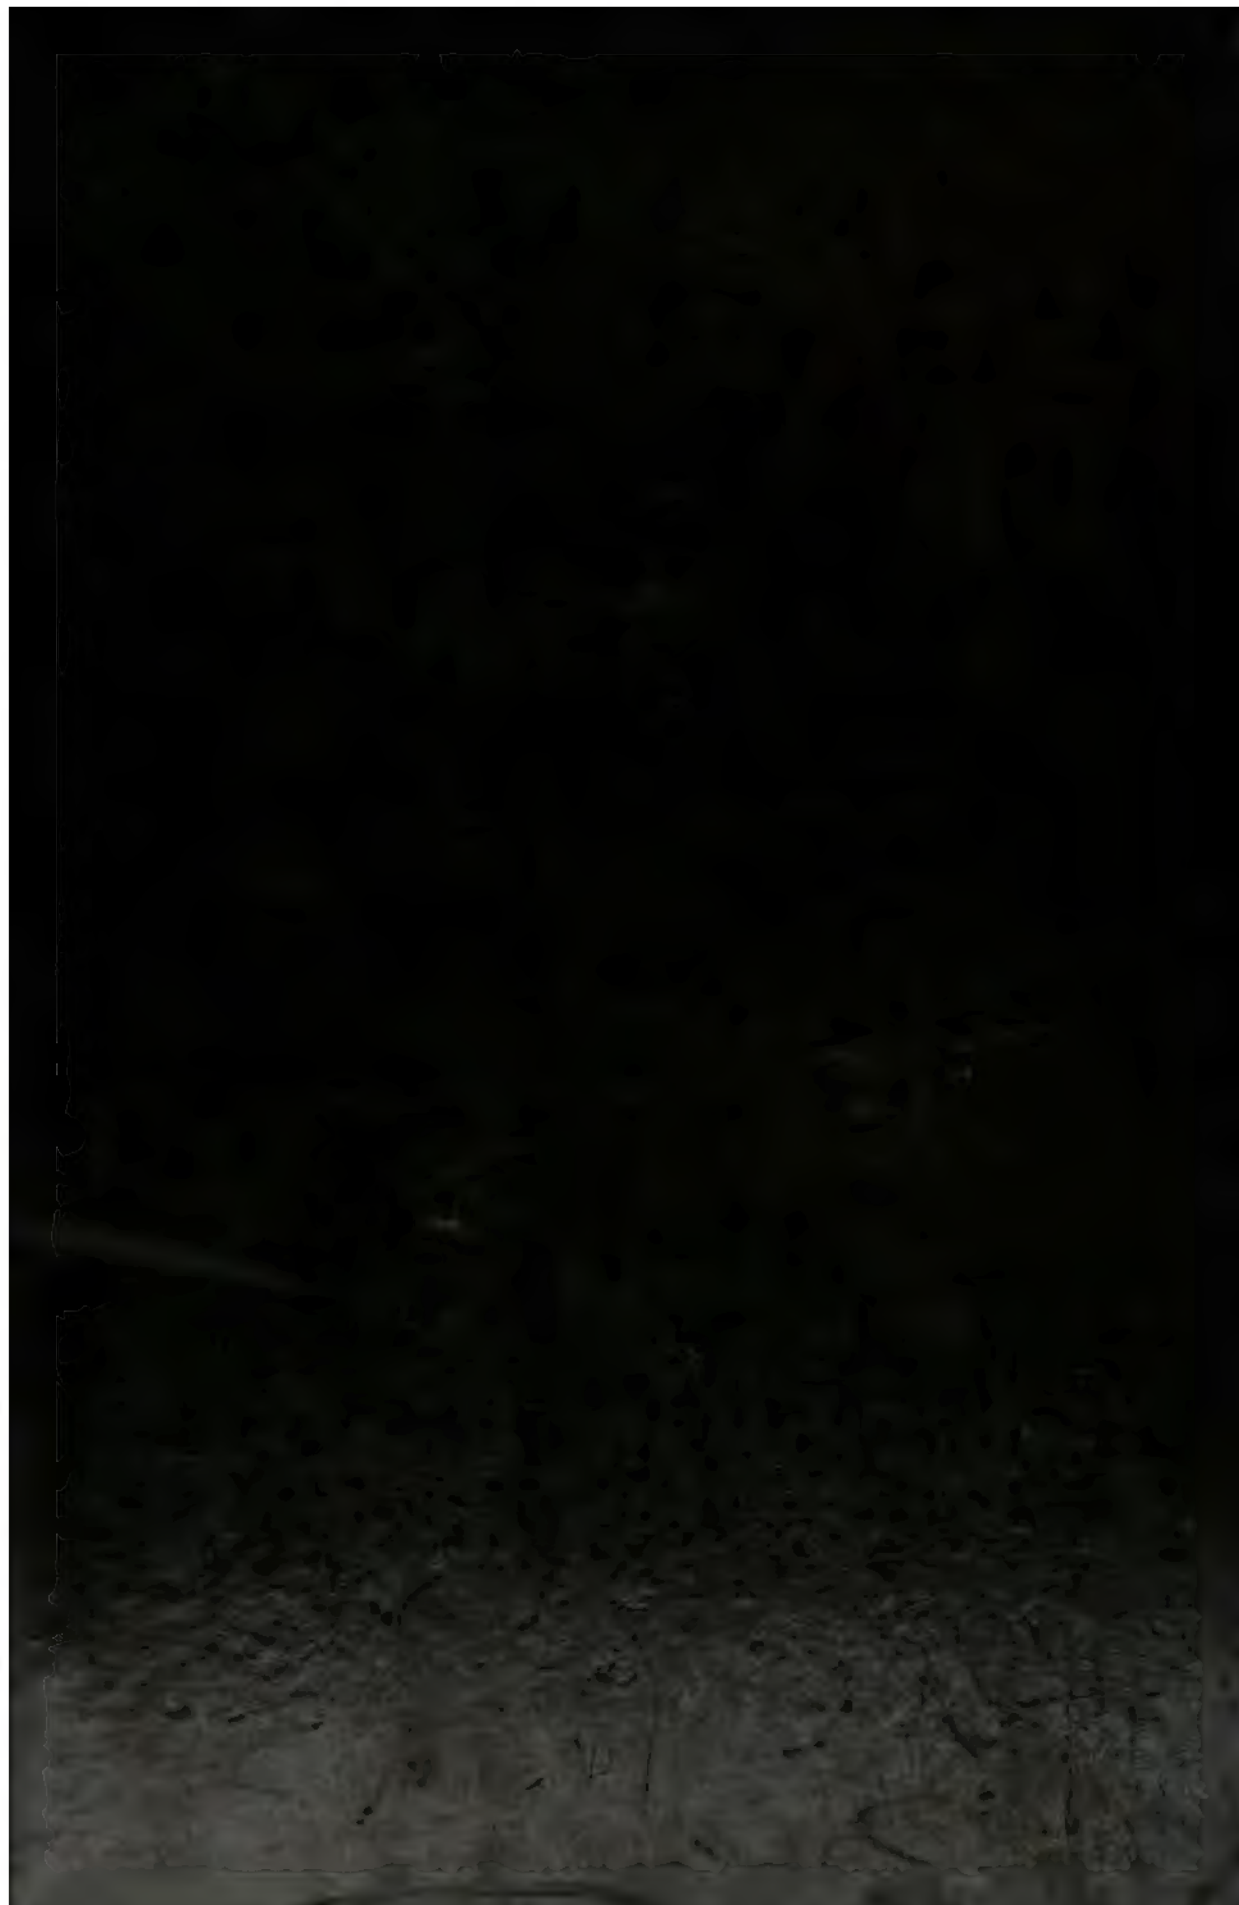

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

GENERAL CONSIDERATIONS ON THE DIETETIC TREATMENT OF DISEASES OF THE STOMACH AND INTESTINE.*

BY PROFESSOR DUJARDIN-BEAUMETZ, Paris, France.

GENTLEMEN:—I am well aware that I am about to take up one of the most difficult topics connected with hygienic therapeutics, but such is its importance that you will permit me to dwell at some length on

this subject of diet in diseases of the stomach. It may be affirmed that the majority of gastric affections are tributary to an exclusive treatment based on hygiene, and that in the therapy of these diseases pharmaceutical agents play only a secondary rôle.

To give method to what I have to say, I shall proceed after the following order: I shall begin by establishing the bases on which you may institute the dietetic regimen of diseases of the stomach, and this will be the theme of the present lecture. Then, in another lecture, I shall apply these general considerations to each of the stomach disorders in particular.

Two modes of procedure are at the disposal of the practitioner to guide him in the study of affections of the stomach,—the clin-

* Two lectures on Alimentary Therapeutics, delivered in the Cochin Hospital. Printed from advance sheets.

ical methods, properly so called, and the more strictly scientific methods, which are addressed at once to the stomach. The clinical methods were the only ones which we possessed till Kussmaul's discovery enabled us to study directly the gastric functions. They consist in the palpation and percussioh of the stomachal region, in an attentive interrogation of the patient, and in an examination of the vomitus and dejecta. We thus used to obtain the only signs that could guide us in the diagnosis of gastric affections.

These signs, from the particular point of view of the functional working of the stomach, were, it must be admitted, of doubtful exactness. The patient can give you but very uncertain information concerning the precise duration of the stomachal digestion, and the repugnance which he often experiences for certain articles of food is especially a matter of habit and custom, or, it may be, of a particular idiosyncrasy. I once knew a patient who could not eat *veal kidney* without veritable symptoms of poisoning; others experience similar effects from eggs, and the list of cases of the kind might be considerably augmented.

Recall to your mind in this connection the modifications which pregnancy effects in the digestibility of certain alimentary substances, also the still stranger tolerance or intolerance which some nervous and hysterical persons manifest for certain articles of food, and you will agree with me that if the ordinary clinical processes are of use in the study of the way the stomach performs its functions, they lack precision.

Hence it is that we gladly welcome the more scientific methods which come to us from Germany, and of which Leube has been the most ardent and able expounder,—methods which consist in directly examining the

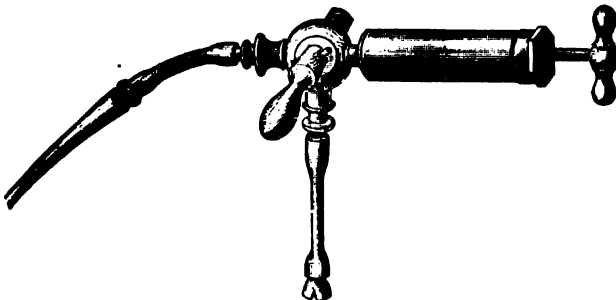

mucous membrane of the stomach and its contents. All these processes are based on the employment of the stomach sound and explorers, and comprehend two distinct acts,—examination of the duration of digestion and examination of the gastric juice.

Let us commence with means used to ascertain the duration of the digestion. According to Leube, a healthy stomach ought in seven hours to have digested a plate of soup, a large slice of beefsteak, and a small wheaten loaf. The liquid of a lavage of the stomach, made after that lapse of time, ought to be absolutely clear, if the stomach is doing its work well. Kretschy makes a single reservation to the rule laid down by Leube,—during menstruation in the female the duration of the digestion may exceed seven hours.

But the examination of the gastric juice requires multiple and somewhat difficult processes, and we have here to study, on the one hand, the acidity of the gastric juice, and, on the other, its digestive power. Before entering on the consideration of these two questions, I must briefly point out the methods in use for obtaining gastric juice, and here again we shall have to study the two following points: how to extract gastric juice from the stomach, and how to make the mucous membrane of the stomach secrete this juice.

To obtain gastric juice from the stomach we have two methods,—that of the sound and the sponge method. If you wish to use the sound, the ordinary siphon-tube will answer the purpose, or, better still, the stomach-pump. I here place before you the one which I ordinarily use. This instrument, constructed by Collin, is very simple and very ingenious, and it suffices to turn the swivel which fixes the syringe to make it communicate either with the stomach or with an outward receptacle (Fig. 1).

FIG. 1.

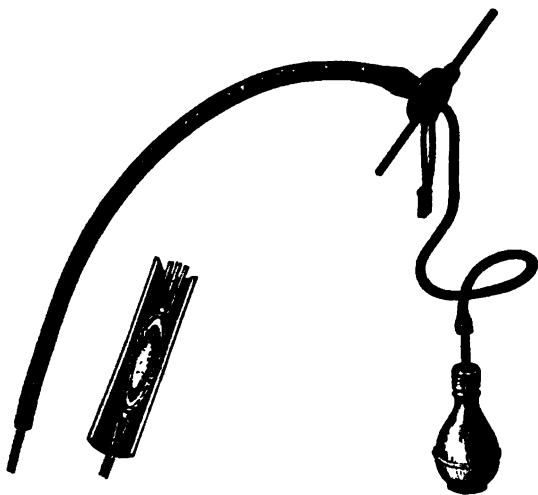

Leube employs a soft rubber sound, six millimetres in diameter, the parietes of which are two millimetres thick, which is introduced

into the gastric cavity, and by means of the stomach-pump, with which it is connected, the contents of the stomach are extracted.

Ewald makes use of a very handy method. He passes down into the stomach a soft rubber catheter scarcely larger than a good-sized urethral sound, and seventy centimetres long. This is introduced nearly the whole length, when he causes the patient to make an effort at vomiting, and at the moment that the liquid appears at the upper extremity of the sound, he seizes the latter with his fingers and quickly withdraws it from the stomach. He then blows into a wineglass the liquid which the catheter contains.

I have myself constructed a stomach-explorer, made for me by Galante, and which I here place before you (Fig. 2). It compre-

FIG. 2.

hends, as you see, a stomach-sound precisely similar to the tube of Debove, having a length of half a metre. In the interior of this tube is a little glass bulb, perforated at both ends, to whose lower extremity is attached a little rubber tube to put the bulb in communication with the mucous membrane of the stomach. The narrow upper extremity of the glass bulb is adapted to another rubber tube, which is much longer, and ends in a flask-shaped rubber ball similar to that which makes a part of an ordinary spray-producer. Finally, a stout string enables us easily to withdraw the glass reservoir. The mechanism of this apparatus is easily understood. You introduce the tube into the interior of the stomach, then, by means of the rubber ball, you exhaust the air in the glass bulb, which then admits gastric juice; then you withdraw the sound. When once the tube is out of the stomach, you remove the glass bulb by means of the string, and empty the gastric juice which you have extracted into a watch-glass by means of pressure made on the rubber ball. The ap-

paratus is one of the most simple, and its introduction and removal are exceedingly easy, especially in individuals who are used to the stomach-tube.

In connection with the foregoing methods, consisting in stomach catheterization, the sponge method deserves mention, being a process which is very simple, and very much employed in Germany, and which we owe to Edinger. Little bits of sponges enveloped in gelatin are attached to the extremity of a long thread. The patient swallows the sponge while fasting. It is allowed to remain half an hour in the stomach, then is withdrawn by means of the thread, and the contents squeezed into a watch-glass for testing.

If you have not the prepared sponges, such as are made in Germany, you can very easily replace them by the following means. You take one of those gelatin-capsules, divided into two parts, encased the one in the other, and known under the name of *Lehuby capsules*. You place in the interior of the capsule a little sponge, to which is firmly attached a long silk thread, which is made to pass through the second part of the capsule, and the two hemispheres of the capsule are then firmly joined together, and are ready for use. The gelatin-capsule is soon dissolved in the stomach, and becomes impregnated with the gastric juice.

The sponge process is more painful than that of the sound. The object of resorting to this method is to do away with the necessity of the introduction of a tube into the interior of the stomach, but the deglutition of a sponge held by a thread, and which has to remain half an hour in the stomach, produces more nausea and vomiting than the sojourn of a sound. I have tried these sponges on a good many patients and on myself, and I have reason to abandon the method.

Now that you know the means employed to obtain gastric juice, I will tell you what you must do in order to provoke the secretion of this fluid. You know very well that the stomach, at the moment of your exploration, ought to be entirely empty, as the presence of food in that cavity considerably modifies the reactions of the gastric juice. You must, then, operate when your patient is fasting, and to stimulate the flow of gastric juice, you may employ three processes,—mechanical, chemical, and thermic.

The mechanical processes consist in irritating the gastric mucosa by a foreign body, as the point of a sound or a sponge. The chemical processes consist in the employment

of a solution of bicarbonate of sodium. You begin by washing out the stomach; then you introduce fifty cubic centimetres of a three per cent. solution of bicarbonate of sodium. At the end of a quarter of an hour you add a half-pint of warm water; then you siphon off (or remove by the pump) the contents of the stomach, to which you may apply the proper tests.

These two processes—mechanical and chemical—ought to be abandoned. The first, because it is uncertain; the second, because the bicarbonate of sodium modifies the reactions which you are seeking to elicit from the gastric contents. The thermic processes are now alone employed, and this is the *modus operandi*:

You introduce into the stomach by the siphon one hundred cubic centimetres of ice-water; then you wait ten minutes, and add three hundred cubic centimetres of water at the ordinary temperature. You siphon off the whole, and examine the liquid thus obtained. It is this "thermic" process which I am about to exemplify in the patient now before you. You have seen with what facility we have been able to accomplish our object, owing to the handy arrangement of the stomach-pump, which, by the rotation of the handle which fixes it, enables us to inject liquid into or withdraw it from the stomach.

We have, then, according to the formal directions of Leube, introduced one hundred cubic centimetres of ice-water into the stomach. We have waited ten minutes, then withdrawn the liquid, which I now place before you, and this it is which we shall now examine. We apply to this liquid two orders of tests,—the one intended to determine its digestive power, the other to ascertain the presence or absence of hydrochloric acid in the gastric juice.

I shall pass briefly over the first order of tests, which belong to the province of chemical researches, and consist in practising artificial digestion with the fluid extracted from the stomach. You take a certain quantity of this liquid; you add a little hydrochloric acid; then you introduce some coagulated albumen in the form of little cubes, whose weight you know. You put the whole in an oven heated to 40° C., and at the end of a certain time you estimate the quantity of albumen transformed into peptone; in a word, you perform an artificial digestion with this gastric fluid. This method, advised by Leube, can only be applied in exceptional cases, and is not to be commended as a practical method.

This is not so, however, with the processes put in usage to detect the presence of hydrochloric acid in the gastric juice. It is to Von den Velden that we are indebted for the most valuable contributions pertaining to this subject. After having insisted on the necessity of the presence of hydrochloric acid in the gastric juice to enable the stomachal digestion to go on, this clinical physiologist has laid down the law that when hydrochloric acid is wanting, its absence is due to a cancerous neoplasia in the stomach. There is, then, as you see, from the point of view of the diagnosis and prognosis of affections of the stomach, a considerable importance in determining the presence or absence of hydrochloric acid.

Three reagents have been proposed by Von den Velden,—methyl violet, which, under the influence of hydrochloric acid, passes from violet to blue; tropæoline, which changes from yellow to carmine-red; and fuchsine, which loses its red color altogether. A few words about these various reagents.

Tropæoline is a coloring substance which is obtained from coal-tar, and which owes its name to the fact that the colors which are derived from it resemble those of the nasturtium (*Tropæolum majus*). There are several kinds of tropæoline, which are designated under the names of tropæoline o, oo, ooo. It is the tropæoline oo of which you should make use. In France you can substitute for the German tropæoline a similar substance, to which is given the name *Poirier's orange*, from the name of the Poirier manufactory where are prepared the dye-stuffs derived from aniline; and as there are many shades of Poirier orange, it is the *orange No. 4* which corresponds to the tropæoline oo. You will make with the tropæoline oo, or the Poirier orange No. 4, a one per cent. solution.

As for fuchsine, a test solution is made of 2 or 3 centigrammes per 1000; but this reagent ought not to be employed for the three following reasons: first, because it is not a very sensitive test; second, because the decoloration is slow in being produced; lastly, because it is always difficult for the eye to decide if the decoloration is more or less complete. There remain, then, the two processes which are less open to objection,—that of methyl violet and of tropæoline.

In using the methyl violet test, you take two test-tubes. You place in these two tubes fifty cubic centimetres of distilled water, in which you deposit two drops of a two per cent. solution of methyl violet. Then you let

fall, drop by drop, in one of the tubes the liquid resulting from the lavage of the stomach, while in the other tube you drop an equal quantity of pure water.

I here show you this test, and you see how delicate it is, and while one of the tubes remains violet, the liquid in the other has turned quite blue. This test enables us to detect as small a proportion of hydrochloric acid as 1.5 per 1000.

The tropæoline test is even more delicate, and it presents the great advantage that lactic acid gives a much more gradual change of color. This is the mode of proceeding :

You take two watch-glasses of equal capacity, which you place on white paper, or on a square of white porcelain. Into one of these watch-glasses you insert by means of a pipette a given quantity of the liquid from the stomach, previously filtered. Into the other you introduce an equal quantity of water ; then you let fall by means of a dropper into the two watch-glasses an equal number of drops of the solutions of tropæoline oo, or of the Poirier orange No. 4 (the one per cent. solution). It is easy for you to see how bright is the change of color, and while the contents of one of the watch-glasses keep their yellow hue, the other takes on a very marked carmine-red tint. To these tests Uffelman has added still two other processes ; the one is based on the modification which the coloring-matters of wine undergo under the influence of hydrochloric acid. Uffelman practises this test in the following way. He takes one cubic centimetre of young Bordeaux wine, and adds three cubic centimetres of alcohol and glycerin. He thus obtains an almost complete decoloration, and it takes the merest trace of hydrochloric acid to give a red color to the mixture.

The other reagent proposed by Uffelman consists of a two per cent. solution of phenic acid, to which is added one drop of liquor ferri perchloridi. You thus obtain a blue-colored liquid. If to this solution you add a little hydrochloric acid, the color disappears. If you introduce lactic acid, the liquid becomes yellowish ; if butyric, it becomes milky.

Uffelman's tests are less employed than those of Von den Velden, and the latter are certainly the most practical. It now remains to determine the diagnostic value of these tests.

In France these researches have been received with some degree of scorn, and few clinicians have undertaken to repeat these experiments of the German physicians, preferring

still to follow the traditional methods. I think that there is little justification for this scorn, for if the anamnestic signs and symptoms furnished by the patient himself are capable of guiding us in our diagnosis, it is silly to reject methods which may in a certain measure confirm our diagnosis. The absence of free hydrochloric acid in the stomach is an important sign. I am well aware that this acid has been found to be absent in other diseases besides cancer, and Uffelman and Schillhart have proved this to be sometimes the case in dilatation of the stomach and in certain fevers, but the evidence is sufficient almost to warrant us in excluding all idea of cancer of the stomach when hydrochloric acid has been proved to be present in the gastric juice, and the interesting observation of Roose where this acid continued to be present in the gastric secretion till the death of the patient, which happened from cancer of the pylorus, is altogether exceptional.*

I have then entered with alacrity on the path marked out by our *confrères* of Germany. It is a line of investigation which they are pursuing with success, every day perfecting their methods. Thus it is that Ewald has pushed farther than any one else the inquiry at what moment in the digestive process the different acids of the stomach make their appearance. He has been led to admit three digestive periods. In the first, which lasts from ten to thirty minutes, lactic acid is found in the stomach. In the second, both hydrochloric and lactic acids are found. In the third, there is free hydrochloric acid, and this is noted one hour after the ingestion of food. Hence, Ewald advises that in the diagnosis of stomach affections one should always take due account of the four following circumstances : 1. Of the energy of the acid reaction ; 2. Of the presence or absence of free acid ; 3. Of the nature of this acid ; 4. Of its digestive power on albuminoid substances and carbohydrates.

Before finishing these general considerations, I must say a few words concerning the general line of treatment employed in Germany, and in particular by Leube, in stomach affections.

Leube's therapeutic system is based on the employment of lavage of the stomach, and on this physiological axiom, that at the end of

* Roose, "Cancer of the Pylorus, with Persistence of Hydrochloric Acid in the Gastric Juice till the Death of the Patient" (*Revue Méd. de Louvain*, January, 1886, p. 20).

seven hours the stomach ought to be entirely rid of the food of the previous meal.

Leube has also established four modes of dieting, or, as we would say, dietary regimens, to which I shall briefly allude, borrowing from the excellent thesis of my pupil, Deschamps, on "Gastric Therapeutics in Germany."*

The first regimen consists of broth of meat-juice, of milk, and of eggs, soft-boiled and raw. These, according to Leube, are the most digestible of all foods. I call your attention to the order in which I have enumerated them. This order is, according to Leube, that of their digestibility.

As for drinks, nothing should be taken but pure water, or water slightly charged with carbonic acid; this regimen is suitable for beginning the treatment of chronic catarrh of the stomach.

In the second regimen we find (and here, too, in the order of their digestibility) boiled calves' brains and boiled thymus, boiled chicken, boiled pigeon, and you may add milk porridge, made with tapioca and whipped eggs, and calves' feet.

In the third regimen you will supplement these foods by very rare beefsteak and raw bacon. Leube dwells particularly on the mode of preparation of beefsteak. He directs to take a slice from the rump; this must be well pounded and then scraped with a spoon till the pulp is all scraped out; cook the pulp rapidly with fresh butter.

The fourth regimen comprehends a great number of alimentary substances, such as roast pigeon, venison, partridge, rare-done roast beef (to be eaten preferably cold), roast veal, and macaroni. Here for the first time wine is permitted, but in very small quantity. Vegetables in moderation, a very little salad, and still less of those stewed fruits which the Germans are always in the habit of serving with roast beef.

Such are the dietetic rules followed in Germany for the cure of affections of the stomach.

Now that you know on what basis are founded the dietetics of diseases of the stomach, we may study the regimen proper of each of these affections. This is what I shall now do.

We have already seen on what scientific basis we may establish the dietetics of the stomach. We will now apply these general considerations to the affections of the stomach in particular, beginning with cancer.

Cancer of the stomach has not, properly

speaking, any special alimentary hygiene, and according to the seat, the variety of the morbid growth, the more or less rapid march of the affection, the symptoms and treatment are variable. But what you ought specially to keep in mind is that it is quite possible in the case of cancers of the stomach of wide extent to preserve the almost complete integrity of the digestive functions, and in a recent communication to the Society of the Hospitals, I have reported several cases which have passed under your own observation.†

You remember that man who lately occupied No. 17 ward, Beau; he was profoundly cachectic, and had in the region of the stomach a tumor of whose nature we were not much in doubt. This patient received, at his own solicitation, every day a salad of hard-boiled eggs, and for a month he made of this indigestible food his only sustenance; he died, and the autopsy fully confirmed our diagnosis, disclosing the existence of a spreading cancer, which had involved almost the whole of the stomach.

You also remember the female patient who entered our service for incessant vomiting and severe pain in the region of the stomach. Thanks to lavage, the functions of that viscus were restored to such a degree that the patient was able for a year to resume her ordinary diet. She entered anew our service, and suddenly succumbed. At the autopsy we found a perforation of the stomach in the centre of a cancerous degeneration. The annals of medicine abound in facts of this kind, and it may be affirmed that almost complete integrity (at least in appearance) of the functions of the stomach may coexist with the most advanced stages of the evolution of carcinomatous affections of this organ.

Here, then, you should allow yourself to be guided by the desires of your patient, while insisting at the same time that he shall take his food in a thoroughly boiled or pulpified state, and make choice of vegetable and starchy foods rather than such as are azotized and fatty. We base the exclusion of these latter aliments on the fact that the gastric juice, as I have already told you, in cases of cancer of the stomach, in losing its hydrochloric acid, loses its digestive properties on albuminoid matters.

• If the rules of dietetics are uncertain in cancer, it is not so in the treatment of ulcer

† Dujardin-Beaumetz, "On the Prognosis of Cancer of the Stomach." (*Bull. et Mem. de la Soc. des Hôpitaux*, 3d series, p. 129)

of the stomach; and Cruveilhier has won for himself lasting renown by having been the first to describe the malady and to find the remedy. This remedy, as you know, is milk diet, carried out in all its rigorousness; on this the life of the patient depends, for if he deviates from this regimen mortal hemorrhages may ensue.

Debove, to neutralize the digestive action of the gastric juice on the mucous membrane proper of the stomach, and to prevent all digestive operations in that cavity, recommends to give from 30 to 40 grammes a day of bicarbonate of sodium to the patient. I believe that such doses are not without harmful effects, and approve of the practice of Lucca, of Naples, who gives his patients milk made alkaline by lime-water.

It is only gradually, remember, that you should return to the ordinary diet, beginning with the starchy articles of food and going on to meat under its most digestible form,—that of meat-powder.

Milk, and an exclusive milk diet, is also the most active curative means in chronic catarrh of the stomach,—a disease which is almost always developed under the influence of alcoholic excesses. In this gastritis of the drunkard you observe two stages: in the first, there is at the outset exaggeration of the acid secretions of the stomach, producing pyrosis and cardialgia; in the second, there is cessation of the secretion of the gastric juice and production of mucus; this is the period of *pituitous catarrh*. In both periods you should employ no other dietetic regimen but milk, taking care always to add to the milk some alkaline water or bicarbonate of sodium.

As the sudden abandonment of all alcoholic stimulants often induces in these patients trembling and grave nervous disorders, you may in the first periods of chronic gastritis employ with advantage those fermented milks—kefir or galazyme—of which I have spoken while on the subject of complete aliments; then you may gradually return to the ordinary diet, taking for your basis the different regimens which Leube has established for the cure of stomach affections.

But for many years, if not for a whole lifetime, the patient ought to abstain from every kind of alcoholic beverage, and drink nothing with meals but milk. This is a requirement very difficult of execution in the case of our laboring classes; hence you will continually see these patients, after having got well at the hospital, come back again for

treatment by reason of having resumed their habits of intemperance. Never was anything more true than the common saying about the drunkard's oath (made only to be broken). I come now to the alimentary hygiene of gastrectasia.

Dilatation of the stomach, since Bouchard's notable researches thereon, has played a preponderant rôle in the pathology of gastric diseases. It deserves, then, to arrest our attention for a few minutes while we consider the dietetic treatment of this malady.

Struck by the fact that substances introduced into the stomach sojourn there an abnormally long time, and give rise by such sojourn to a characteristic swashing sound (*bruit de clapotement*), it has been deemed most rational to employ a dry diet in this affection, and to this system of cure has been applied the name of *xerophagia*. Vaunted anciently by Hippocrates, by Petronius, by Asclepiades, by Ettmüller, and more recently by Chomel, as the most efficacious treatment for what the latter improperly called *the dyspepsia of liquids*, this dry diet regimen has found an earnest advocate in our friend and colleague, Huchard. He recommends that the patient shall drink only a small tumblerful (8 to 12 ounces) at each meal, and none between meals; that he shall discard all foods that contain much water, and take no soups unless they are made very thick. He forbids fruits, and advises roast meats, eggs, and vegetables.

But it is to Bouchard that we are indebted for the most precise rules as to the dietetics of dilatation of the stomach. You will find in the remarkable thesis of my excellent interne, Dr. Paul Le Gendre, complete details as to Bouchard's regimen, and taking that as our standard authority, we will examine successively the drinks and foods of patients in gastrectasia.

As for drinks, Bouchard allows only 375 grammes (or about 12 fluidounces) with the breakfast and dinner, and none between meals. All beverages should be avoided which have a tendency to ferment; red wines should be interdicted, and the patient allowed only the table mineral waters, or water containing one-third or one-fourth part of beer or white wine, or a teaspoonful of brandy. It must be insisted on that the patient shall not drink between meals.

As for foods, all fatty substances must be abandoned; the patient must be allowed only bread crust or toast, the interval between repasts must be as long as possible, and there should be at least nine hours between the two

meals, breakfast and dinner, and fifteen hours between dinner and breakfast.

In my own practice I pursue a somewhat different course, and these are the rules which I apply to the treatment of gastrectasia. I divide the victims of this affection into two great classes, those who have diarrhœa and those who are constipated.

For the first I order a purely vegetable diet,—starchy foods, vegetables, and fruits. The amylaceous substances ought to be ingested in a thoroughly cooked condition; the vegetables should be very tender and well done, and the fruits stewed. I absolutely suppress meat and eggs. For a drink, I order Bavarian or Pilsen beer, or liquid malt. I insist upon a long interval between meals, and limit the drinks to ten fluidounces at each meal.

I add to this purely vegetable regimen the employment of carbon-bisulphide water as an antiseptic. This solution, of which I have already spoken in my "New Medications," renders me great service. The formula is as follows:

R Pure sulphide of carbon, f3vi;
Essence of peppermint, gtt. 1;
Water, f3xiii.

Mix in a flask having the capacity of five hundred cubic centimetres, shake, and let settle. Use the clear supernatant solution, and renew the water as fast as you pour off from the flask for medicinal use.

I give daily from four to eight tablespoonfuls of this solution at meal-time and between meals. Each dose is taken with half a glass of milk or beer.

In the case of patients with dilated stomachs, who are constipated, I adopt the treatment of Bouchard,—that is to say, I permit roast meats. I order toasted bread and fruits, and especially peaches and grapes. I add light saline purgatives, such as, in particular, the natural mineral waters.

In both classes of patients hydrotherapy renders us great service. As for lavage of the stomach, it is indicated whenever the dilatation is considerable.

In rigorously submitting your patients to this system of diet, you will considerably ameliorate the state of their stomachs, and you will relieve most of the symptoms due to the gastrectasis, without, however, much modifying the distention of the gastric ventricle.

The alimentary regimen of dyspeptics is very difficult to establish. This word dyspepsia is destined gradually to disappear from nosology, and be replaced by the name of the disease of which the dyspepsia is the symp-

tom; but for the present the term may be accepted for what is generally understood by it.

From the exclusive point of view of dietetics, I divide dyspepsias into three groups,—dyspepsia by excess of gastric juice secretion, dyspepsia by deficiency of secretion, and dyspepsia with sympathetic troubles.

For the first, you will order a purely vegetable diet, composed of bread, vegetables, and fruits. For drink, you will order milk, and you will sometimes allow beer, but never wine.

For dyspeptics with deficiency of secretion of gastric juice, meat and soups are, in my opinion, the best peptogenous agents. You will then order meat, but in a very assimilable form,—that is to say, in the form of powder or pulp. It is here that the meat-choppers and pulpifiers will render you great service. But it is necessary to be very careful about the quantity of meat which you order, and proportion it exactly to the digestive power of the patient whom you are treating. You may prescribe milk, which, by its lactic acid, augments the digestive power of the stomach. You can make use also of the mixture, vaunted by Herzen, of broth and milk. As wine and alcohol augment the acidity of the gastric juice, you will authorize wine, or water to which a little brandy is added. In this dyspepsia by deficiency of gastric juice, the peptones may render you some service when the patient can tolerate them.

For dyspeptics with sympathetic troubles, such as gastric vertigo, you should diminish all the excitations which result from the irritation of the mucous membrane of the stomach, and you will be most likely to do this by making your patient a vegetarian,—*i.e.*, by subjecting him to a regimen of bread, fruits, legumes, and vegetables, and giving him milk for a drink.

As you see, gentlemen, I attribute a considerable importance to a strictly vegetable diet in a great number of diseases of the stomach. Allow me, then, to state the principal points in this dietetic treatment.

In regard to bread, I order the crust rather than the crumb, or, better still, when the patient has good teeth, bread well toasted.

As for amylaceous foods, I recommend mashed potatoes, pea-soup, and bean porridge, Indian-meal puddings, and hominy, oatmeal porridge, and oatmeal cakes, barley gruel, sago, farina, arrow-root, macaroni, etc., in puddings, adapting the regimen to the condition of the patient, whether fat or lean.

Vegetables must before eaten be boiled to a mash ; salads, legumes, spinach, sorrel, green beans, etc., must be cooked till quite tender.

Fruits should be stewed or baked before being eaten, grapes alone being excepted. In this dietary I allow eggs, on condition that they be soft-boiled or eaten raw. For drinks, beer seems to me preferable to wine in a strictly vegetable regimen.

I shall now finish what I have to say on the subject by briefly alluding to the dietetic treatment of diseases of the intestine. I shall concern myself here only with constipation and diarrhœa, two diseases in which diet has a most happy influence. Let us begin with constipation.

Constipation is often tributary to an appropriate alimentary regimen, and it may in truth be said that to the constipated the diet treatment is worth more than the medicinal.

As a general rule, it will be enough simply to augment the quantity of the fœcal matters if you wish to obtain regular stools, and as the excreta are constituted by the waste products of digestion, and in particular by cellulose which escapes the action of the digestive juices, it is for the most part by giving foods containing cellulose in abundance, such as bran bread, green vegetables, salads, spinach, sorrel, tomatoes, etc., that you can by dietetic means promote alvine evacuations. Recall to mind in this connection the singular remark of Voit, who affirms that by examining the fœcal matters deposited along the roads one may judge of the richness of a country. In places where the peasants eat meat, the fœces are hard ; where, on the contrary, the food is of a purely vegetable kind, they are soft, and resemble cow-dung.

To these herbaceous substances, to these green vegetables, you may add certain articles of diet which, in constipation, possess curative properties. Thus, gingerbread eaten in large quantity is very generally laxative ; fruits, and especially grapes, have this quality in a high degree. In the grape-cure, diarrhœa is one of the effects which is reckoned upon with certainty ; melons, oranges, and lemons are used for the same purpose. Baked apples, especially when cooked with molasses, have loosening properties.

But there are two substances which have been especially vaunted in the treatment of constipation,—white mustard-seed and linseed-meal. Didier was the great advocate of white mustard-seed. This laxative agent, which was once very much in vogue, now seems to have gone out of fashion. If it had the advantage

of often determining stools by its presence, it also, in more than one instance, was the cause of intestinal occlusion by the accumulation of these seeds in the intestine.

Flaxseed-meal is a good means for overcoming constipation when taken in the way which I prescribe. You macerate a tablespoonful of the ground seeds in a gill of water, steep an hour, and swallow the whole at meal-time. By all these little means you may succeed in maintaining regularity of the stools, though some obstinate cases resist them altogether. I come now to the dietetic treatment of diarrhœa.

From a dietetic point of view, we should distinguish abdominal fluxes determined by affections of the small intestine from those due to affections of the large intestine. It is especially with reference to the first that diet renders us important service. It will hardly be disputed that in chronic diarrhœas an appropriate dietary regimen is the *sine qua non*. This regimen is altogether based on the employment of the four following alimentary substances : milk, raw meat, peptones, and meat-powders.

Milk occupies the first place in the dietetics of abdominal fluxes, and it is by the milk diet rigorously carried out that you will obtain the mastery of these affections. I know, in fact, of but one form of chronic diarrhœa that is rebellious to this treatment, as it is in fact to all other treatments. I refer to tuberculous diarrhœa. I have said *rigorously carried out*, for infractions of this exclusive regimen perpetuate the diarrhœa instead of curing it, and we often see in our troops who return from the far East the sad consequences of such infractions of the milk diet.

The patient, finding himself a little better, and tired of milk, abandons this regimen, to go back to it again as soon as the disease increases in intensity ; the diarrhœa is perpetuated, and the patient eventually succumbs. First, then, an exclusive milk diet ; then raw meat and meat-powders. I much prefer the meat-powders to the raw meat, but it is necessary to proceed with extreme caution, and proportion the quantities of these azotized aliments to the state of the intestine.

Bazile Ferris preferred the peptones to raw meat and meat-powder, giving them along with the milk diet. You may at times use these peptones with benefit ; then you may, little by little, increase the daily fare of your patient, being guided by your knowledge of the digestibility of the articles of food which you order.

Just as laxative properties have been ascribed to certain aliments, so, also, others have been regarded as constipating. In this connection I may mention quinces, and substances that contain tannin, such as artichokes. White of egg has also been utilized in these cases. All these means are absolutely secondary, and play a doubtful rôle in the cure of diarrhœa.

In the diarrhœa of infancy milk is still the remedial agent *par excellence* (the milk being suited to the age of the infant), and whenever you see in your little patients frequent greenish discharges, be persuaded that this diarrhœa results either from cold or the use of improper food. You well understand that you may augment the constipating properties of the milk by the addition of lime-water, which is very serviceable in such cases.

I shall finish this course of lectures on alimentary therapeutics by a final lecture on diet in fevers.

CRITICAL OBSERVATIONS AND EXPERIMENTAL STUDIES ON THE INFLUENCE OF PHARMACOLOGICAL AGENTS ON PERIPHERAL VESSELS.*

BY PROF. R. KOBERT.†

PART I.

IN the same way that Schmiedeberg and Bunge‡ studied on the excised kidney the formation of hippuric acid, and W. von Schroeder§ and W. Salomon|| on the excised liver the formation of urea, may we also study the action of pharmacological agents on other organs thus kept artificially in functional activity.

This action may manifest itself in affecting the movements and variations in volume of the respective organ, in increasing or decreasing its secretion if it be a gland, and, finally, in altering the vascular calibre of arteries and veins.

Investigations relating to the *movements* of excised, or at least as well as possible isolated, organs have been instituted for physiological and pharmacological purposes on the iris of cold- and warm-blooded animals; on the uri-

nary bladder and the œsophagus of the frog; on the wing-membrane of the bat; on the external ear of the rabbit; on the heart of reptiles, amphibious animals, and fish; on skeleton-muscles of dogs; and on the intestines, stomach, and uterus of various warm-blooded animals. Critically viewed, however, it is clear that the interpretation of phenomena thus observed cannot be otherwise but arbitrary until the technique of keeping an organ alive—in most cases this consists only in conducting a uniform current of adequate blood through the isolated organ—has been sufficiently studied and perfected. And this cannot, of course, be accomplished in a few isolated trials.

In view of the scanty experimental material in existence, I thought it appropriate to institute a more extensive series of experiments on the action of the most well-known pharmacological agents, for the sole purpose of studying the *alterations in the velocity of the blood-current*. I must remark that sufficiently numerous preceding experiments have demonstrated that my *modus operandi* of blood-transfusion insures the vitality of the respective organs for several hours, and procures a uniform sanguineous current.

The first trials with conduction of blood through surviving organs of warm-blooded animals appear to have been made by Alexander Schmidt,¶ under the direction of Ludwig in Leipzig. He conducted, with an approximately equal pressure, the blood of a dog through a dog's kidney placed in a heat-box, in order to study the generation of carbonic acid. These experiments, however, did not produce any results of pharmacological interest. The subsequent labors of P. Heyer,** and particularly of A. Mosso,†† on the other hand, which were likewise executed at the Leipzig Institute, have attained a high degree of perfection and claim our interest. The pharmacological results of these labors refer to nicotine, atropine, carbonic oxide, hydrate of chloral, and cyanide of potassium. Mosso continued, later on, these experiments in Italy, with various modifications; but these publications have never been seen by me.

* A brief abstract of the results of this work has appeared in the *Tageblatt der Strassburger Naturforscherversammlung* (Strassburg, Trübner, 1885), p. 425.

†† "Some New Properties of Vascular Walls." Proceedings of the Royal Saxonian Society of Sciences, Leipzig, vol. xxvi., 1874, p. 305.

In 1877, J. Bernstein* advanced the following axiom, which held true also of the pharmacological science: Irritation of the sciatic nerve of a dog's thigh traversed by the blood of a (curarized) dog does not produce vascular contraction any more than during life, but provokes vascular dilatation. As Sadler† and Gaskell,‡ employing the same plan of blood-conduction, did not observe any alterations in the width of the current, Bernstein is inclined to attribute the vascular dilatation observed by him to the vessels of the skin. Later, in 1879, Filehne§ made some interesting experiments with the conduction of blood through a rabbit's ear. These experiments showed the action of nitrite of amyl to be of central origin. In 1880, Salvioli|| demonstrated that by conducting blood through excised sections of the intestines certain phenomena of life could be accurately studied. He mentioned as such the absorption of peptone, the intestinal peristaltic movements, the increase of the ascending blood-current in poisoning with atropine and tincture of opium, and the decrease of the current in nicotine-poisoning. In the same manner, Albertoni¶ investigated later the action of cotoin on the intestines, and found that this agent increases the quantity of blood traversing the bowels. By blood-conduction through the posterior extremities of the dog, N. Rubenow** showed in 1880 that an infusion of adonis vernalis contracts temporarily the blood-vessels independently of the central nervous system.

In 1883, Abelés, experimenting with blood-conduction on excised kidneys, arrived at the conclusion that urea increases the blood-current in this organ. Of high value for the knowledge of results obtained by blood-conduction are also the experiments of M. von Frey†† and M. Gruber, in which the technique has reached the highest degree of perfection. In these painstaking works (which appeared after the conclusion of my pertinent researches) it was also shown that during the

conduction the blood becomes essentially altered and ultimately unfit for use.

These are the most important data which have been recorded in regard to experiments on surviving organs of warm-blooded animals and the influence of pharmacological agents on such organs. The few serviceable experiments instituted with blood-conduction on *cold-blooded animals*, especially on frogs and turtles, will be referred to below. They are, however, of secondary importance, and are only of value when viewed as experiments parallel to those instituted on warm-blooded animals. The following are the two principal objections which must be urged against these experiments: 1. In no instance was there but a single organ traversed by the blood, but invariably the entire body, excepting the heart; hence it was impossible to tell which organ had caused the increase and decrease of the traversing current observed by the experimenter. 2. The medium of conduction used was in nearly every instance a solution of chloride of sodium, which was, besides, often mixed with blood foreign to the animal. Subjected to such a treatment the vascular walls, which in this connection play of course the most essential rôle, rapidly underwent pathological changes or even lost their vital energy. Although the defects of these procedures have been openly exposed by Glax and Klemensiewicz‡‡ in 1882, such researches are nevertheless constantly cited as embodying a scientific testimony. The mentioned experimenters showed that frogs treated in the manner indicated became invariably œdematous, even when by opening the auricles the flowing off of the traversing liquid had been greatly favored and the pressure employed was an exceedingly low one. The velocity of the off-flowing liquid decreases, of course, simultaneously with the formation of the œdema, provided the pressure of the incoming liquid remains uniform. To avert these drawbacks two procedures in particular have been proposed. The first is that of Sidney Ringer§§ and H. G. Beyer,|| and consists in substituting for the solution of chloride of sodium a mixture of 100 c.c. of a seventy-five per cent. solution of chloride of sodium + 5 c.c. of a solution of chloride of

calcium (1 to 390) + 2.5 c.c. of five per cent. solution of bicarbonate of sodium + 0.75 c.c. of a one per cent. solution of chlorate of potassium. This substitution is in many instances to be regarded as a decided improvement. (The results obtained with this solution differ, however, from those obtained with blood, as I shall show in the second part of my paper.)

The second plan proposed for the stated purpose was the employment of an artificial heart.

This substitution has two advantages,—first, the circulation was made to closely resemble the natural state, and then the otherwise inevitable thrombosis and subsequent formation of fibrin, resulting from settling (sinking) blood-corpuscles, was largely prevented. This insertion of an artificial heart has been proposed by L. T. Stevens and F. S. Lee.* Independently of these authors, I also made use of an intermittent pressure in various experiments upon frogs, in which I employed Ewald's† respiration apparatus.

On microscopic inspection of sections of the mesentery, or the web of frog, transfused in the manner indicated, pulsation could be made out even in the smallest vessels, and was seen to closely resemble the natural act, and to prevent the sinking of blood-corpuscles to a certain extent. Such pressure-intermissions imitative of cardiac action are, as M. Gruber‡ has lately shown, also of extraordinary value for the transfusion of organs of warm-blooded animals. This observer found that in transfusions without an artificial heart the pressure is to be gradually increased, if the current is intended to be kept up,—a precaution wholly unnecessary when an artificial heart is inserted.

As to the technique of my experiments on warm-blooded animals, I invariably used blood and organs of the same species of animals which was experimented upon. The principal animals of experimentation were dogs, rabbits, sheep, calves, hogs, and horses, and the principal organs the kidney, the

spleen, the liver, the lower extremities, the entire posterior part, the intestines, and the uterus. Dogs and rabbits (in Dorpat also calves) were always killed immediately before the experiment; the other animals were killed in the slaughter-house, and the respective organs, together with the blood, were brought into the Pharmacological Institute, and used at once. By special provision, the animal temperature of these organs was kept up as well as possible. Diluted§ or strange blood was never used, as I soon found that the latter showed a toxic action. This statement I feel called upon to emphasize in opposition to Salvioli, who employed strange blood mixed with a seventy per cent. solution of chloride of sodium. The organ was enclosed in a heat-box, having a glass cover, the temperature being retained constant at 38° C. The blood had previously been warmed by a similar process. A febrile rise of temperature—39.5° C. and more—is to be carefully guarded against as a certain source of disturbance, due probably to the contraction of the walls of the larger arteries, as observed by Roy and Grünhagen. The arterialization was effected by shaking the blood, and thus mixing it with air.

The concomitant lowering of temperature of the blood was immaterial, as the proper temperature could be reached again before the blood re-entered the organ. The blood reservoir was a double one,—a smaller one for poisoned blood and a larger one (containing a litre) for normal blood. Both communicated above with an air-filled gasometer, the pressure of which was kept at a constant level by means of a Mariotte bottle. This pressure corresponded always to the pressure indicated by the animal during life. By means of a valve I was enabled to supplant the normal blood-current by a poisoned one, and *vice versa*, without interruption of the circulation or alteration of the pressure. Care was taken not to mix the blood flowing from the vein, during the poisoning or immediately after, with the normal current. These experiments were regarded as available only when the alteration in the velocity of the current produced by an introduced poison *disappeared again under the use of normal blood*. In order to render the latter at all feasible the poisoning lasted only ten minutes or less. In the various similar cases recorded in literature

* The action of intermittent pressure and of defibrinated blood upon the blood-vessels of the frog and the terrapin. "Studies from the Biological Laboratory of the Johns Hopkins University," vol. iii., 1884, No. 2, p. 101. (I am greatly indebted to the Johns Hopkins University for the sending of this paper.)

† Ewald and myself first proposed the use of valves for physiological experiments (*Pflüger's Arch.*, vol. xxxi., 1883, p. 167). This contrivance is undoubtedly a very convenient one, as the valves open spontaneously on the slightest excess of pressure, and still close absolutely tight.

‡ Loc. cit., p. 538.

§ I have detailed below some few successful experiments made with diluted blood on rabbits. The larger majority of these experiments failed, however.

we usually find an omission of the statement that the velocity of the current became normal again after the termination of the poisoning. This neglect detracts largely from the value of such experiments, especially when vascular contraction comes to be considered, as it is well known that at the death of an organ the velocity of the blood-current decreases for various reasons. In my experiments the velocity of the current remained almost constant during the first two hours; *i.e.*, became constant again even after repeated poisoning. It was necessary, however, to slowly raise the pressure five to ten millimetres during the stated time. In experiments which lasted four or more hours, the pressure had to be gradually raised fifteen to twenty millimetres in order to reach again the original velocity of the current.

Another point to be considered is the gradual thickening of blood when flowing from a vein into an open vessel, and when shaken up with air. This alteration I endeavored to eliminate by successive additions of small quantities of weakly alkaline solutions of chloride of sodium (physiological solutions).

As to the proportion between the poison employed and the blood, I used such quantities of the former as would be proportionate to the poisoning of the entire body. Substances being insufficient in this concentration were usually likewise also in doses two to five times as large, and have been designated in the charts as having no influence on the velocity of the current. I believe that the reader will have confidence in my experiment when he sees that a large number of substances were examined in which no alteration of the velocity of the current manifested itself. The occasionally instituted experiments with blood-transfusions, as found in literature, are, I repeat, of little value, for the reason that one doubts whether the experimenter has so far mastered the difficult pertinent technique as to procure a uniformity of the current, even when no toxic agents had been employed.

Another very important point in these researches is to avoid introducing into the blood extracts, greasy substances, strongly acid or strongly alkaline agents, as these alter the velocity of the current by themselves without any additional intoxication. For this reason, then, most of the experiments made with ergotine, extract of digitalis, tinctures, and infusions are without value.

It is well known that in these transfusion experiments the central organs of the nervous

system die first. In my experiments, however, I succeeded, when transfusing posterior parts and keeping alive the lower portion of the spinal cord, in two and even sometimes in four hours, to elicit muscular tetanus in the lower extremities by means of strong interrupted currents. Likewise successful, in the second hour, was Bernstein's experiment,—*i.e.*, increase of the flowing-off quantity under irritation of the sciatic nerve with or without curare. The survival of the kidneys* used for most experiments was proven by the existence of renal pulsation, often very distinct in the second hour, but wholly absent in the third. In other organs this pulsation is less distinct or wholly wanting. In order to convince myself of the vitality of such organs, I used as reagent hydrate of chloral in such great dilution as to barely increase the circulation of fresh organs. If this reaction did not appear after a transfusion of two to three minutes, the organ was regarded as dead and was laid aside.

After the termination of the experiment I often used to examine a portion of the organ microscopically. If the poisoning had not been too intense, the microscopic structure appeared, even after two hours, well preserved, save some small hemorrhagic and oedematous defects.

As to the differential behavior of the single organs towards one and the same poison, we can summarily assert that, excepting the kidney and the liver, all organs react alike qualitatively and almost alike quantitatively. This fact advocates the assumption that the toxic effects obtained in these cases refer solely to the vascular walls and not to another origin, such as the specific tissues of the single organs. The exceptional position of the liver can in this manner be also satisfactorily explained, *viz.*, by the extremely scanty development of muscular tissue in the portal vein. I therefore obtained appreciable results with transfusion, beginning in the hepatic artery, while the transfusion starting from the portal vein led, in most instances, to no results. In the case of the kidney, some few active diuretic agents only make an exception from the above stated rule by acting on this organ more intensely than on others. Of this deviation I shall in some later publication treat in a more detailed manner.

Proceeding now to the significance of the variations in the velocity of the off-flowing current, we find that these may be brought about in the following manner:

* The kidneys cannot well be electrified.

1. *Mechanically*, if the consistency of the blood is increased or decreased, or if the pressure under which the blood enters the organ varies, or, finally, if air-bubbles or clots circulate in the blood-channels. I have succeeded in maintaining the consistency of the current at a pretty constant level by aid of the previously mentioned gradual addition of a solution of chloride of sodium, as can be seen from the pretty identical results obtained at the beginning and end of several experiments, by actual counts of the blood-corpuscles, by determinations of hæmoglobin and dried blood-substance. Any great variations in the pressure of the blood were prevented by a sufficiently large Mariotte bottle. If one of the two blood-vessels was opened for the purpose of filling it and the pressure thus lowered, the blood always flowed in this period without any alteration of pressure from the other vessel into the organ. A neglect of this rule caused always great variations in the velocity of the current.

As to the disturbance of the current by clots and air-bubbles, I found that quite a number of experiments had to be thrown aside on account of these interferences. In this connection, the careful warming of the blood after its first passages is to be viewed as an important factor, as subsequent coagulations are always apt to form.

2. *Thermally*, as sensitive organs like the uterus show reactive alterations of their vascular calibre, even upon variations of the blood-temperature amounting to only a few tenths of a degree. In these cases a good thermostat is of great value, though, after having fully tested my own apparatus, I could usually get along without this instrument.

3. *Chemically*, as in such experiments various factors are apt to alter the chemical relations of the blood. Thus it is particularly difficult to maintain the arterial character of the afflowing (entering) current. I candidly confess that my success in this matter has always been limited to certain boundaries. For, even if the blood be poured into both reservoirs as well arterialized as possible, we still find the blood contained in the larger reservoir changing its nature on account of the constant consumption of oxygen, and this long before it is completely empty. On the other hand, Mosso and Ludwig have shown that variations in the percentages of oxygen and carbonic acid exert a definite influence on the blood-current. I had myself repeatedly the opportunity of confirming the above observation. Another factor which causes

gradual changes in the chemical composition of the blood is the formation of acids, such as lactic acid* and carbaminic acid. I have, therefore, added from time to time some alkaline agent, usually Runge's† alkaline solution of chloride of sodium, with the view of thus counteracting to some extent the disturbing influence of acids upon the velocity of the current. Again, we sometimes observe the formation of methæmoglobin, especially when the blood, the temperature being too high, has dried up on the vascular walls. This formation of methæmoglobin appeared to occasionally act as a disturbing agent in the transfusion of the kidneys.

4. *By neuro-muscular action*,—i.e., by the specific influence exerted on the vascular muscular tissue and on the *ganglionic nerve-apparatus* located in the latter. As there is considerable variance of opinion concerning these nervous structures, and as, on the other hand, they play a most prominent rôle in the proper interpretation and appreciation of all of my experiments, I beg to briefly recall such pertinent items as can be safely regarded as established from both the anatomical and the physiological point of view.

(To be continued in our next issue.)

PNEUMATO-THERAPY.

BY SOLOMÓN SOLIS-COHEN, A.M., M.D.‡

BY pneumato-therapy is meant the utilization in the treatment of disease, of those modifications in the performance of the functions of organic life, which are brought about by modifications of the physical condition of the atmosphere in which the patient is immersed, or of the air he breathes, or of both.

The atmosphere may be modified for therapeutic purposes in respect to its density, its temperature, or its humidity. It is of changes of density only—that is, of pressure phenomena—that I desire to speak this evening.

Changes of atmospheric pressure are used in medicine by either of two methods, which have been respectively termed, the absolute method and the differential method.

An absolute change of atmospheric press-

* *Vide* pertinent observations of M. von Frey, *loc. cit.*, p. 562.

‡ Chief of Clinic Medical Out-Patient Department, Jefferson Medical College Hospital, Philadelphia. Read before Philadelphia County Medical Society, December 8, 1886.

ure, affects both and equally the respired and the surrounding atmosphere. A differential change affects one of these factors only, or both unequally. Differentiation may be made to (directly) affect inspiration only, or expiration only; or it may be made to affect both phases of respiration, equally or unequally, in the same or in opposing directions.

While it is true, that patients may by change of residence to a more or a less elevated region, be subjected to absolute change in atmospheric pressure, yet this is, after all, but one of the factors in climato-therapy, and a brief allusion to the fact is all that properly falls within the scope of the present paper.

The absolute method in pneumato-therapy is applied by means of apparatus termed pneumatic chambers; a number of which have been constructed and are in use at different points in Continental Europe, but I am not aware of any establishment of the kind in English-speaking countries. The first of these was made, after designs by Tabarie, in 1838. The literature of the subject, however, is much older,* Tabarie having made his first communication to the Academy of Sciences at Paris in 1832, and Jounod having presented his first paper in 1835; while even in the eighteenth century, the attention of naturalists had been directed to the effects of condensed air on animal and vegetable life. Tabarie's cabinet could be used only with compressed air. G. Lange modified the apparatus so that rarefied air might also be employed, and so that expiration, if so desired, might be made directly into the outer atmosphere. In this latter respect, we find the first attempt at differentiation. It was in Lange's cabinet that Von Vivenot prosecuted his valuable and laborious researches. Von Liebig designed for the Mack Brothers at Reichenhall a pneumatic chamber said to be the best in existence, while that of Simonoff at St. Petersburg, consisting of a stone chamber and two iron ones, is said to be the most elegant in its appointments. The patient, or a number of patients, having entered one of these appliances, the contained air is then gradually condensed or rarefied by means of a steam-pump; the pressure being gradually restored to the normal after a sitting of from half an hour to two hours or

longer. Special appliances secure proper ventilation, and permit regulation of pressure, of temperature, etc. These chambers are very costly, and their use necessarily restricted to certain resorts. Hence, for a long while, various attempts have been made to construct cheaper and portable apparatus. The portable apparatus utilize the differential method,—that is to say, the air within the lungs is rendered different in pressure from the surrounding atmosphere.

Changes of intra-thoracic air-pressure can of course be obtained without any apparatus whatever. Thus, if, while nostrils and mouth are closed, forced expansion of the chest be made (Müller's experiment), the air within the lungs will be rarefied; and conversely, if, after a full inspiration, the glottis, or the mouth and nostrils, be closed, and an effort made to contract the chest (Valsalva's experiment), assisted, perhaps, by manual compression (Weber's experiment), the intra-pulmonary air will be condensed. A less degree of condensation may be caused by expiring through but partially-closed lips; and a simple contrivance based upon this principle—a narrow tube, with a ball-valve to resist expiration—produces the same effects as expiration into compressed air. It is obvious, however, that the effect of rarefaction can thus be obtained only during a prolongation of the inspiratory phase of the respiratory act, while compression can be brought about only by a baffled or impeded expiration. The respiratory rhythm is completely deranged, the mechanical force employed and developed remains an unknown and variable quantity, while the disturbance of circulation is usually out of all proportion to the therapeutic value of the expedients.

Resort to apparatus for furnishing a supply of condensed or rarefied air is therefore preferable. Simple matter as the construction of such apparatus should seem to be, it was not until 1870 that any practical device at all fulfilling the necessary conditions was made; and not until 1874 that a reliable apparatus was presented to the profession. To Hauke, of Vienna, belongs the credit of having made the first approach to a suitable instrument; and to Waldenburg, of Berlin, is due the honor of having constructed an apparatus which has served as the model of the best of subsequent ones, and of having placed pneumato-therapy upon a firm scientific basis, by patient and accurate physiological and clinical studies.†

* For historical and bibliographical details, see J. Solis-Cohen, "Inhalation: its Therapeutics and Practice," second edition, Philadelphia, 1876; Oertel, "Handbuch der Respiratorischen Therapie," Leipzig, 1882. English translation by J. Burney Yeo, London, 1885.

† "Die Pneumatische Behandlung der Respirations- und Circulations Krankheiten," Berlin, 1875.

In the arrangement of apparatus for the therapeutic use of compressed and rarefied air, two desiderata must be secured with mathematical precision,—1. The pressure must be a known and controllable quantity; 2. It must be constant, or varied only at will. The physical principles involved, are identical with those involved in a study of the physiological effects of pneumato-therapy; depending upon the properties of the gaseous state of matter, the tendency of matter in whatever state to move in the direction of least resistance, and the fact that the effect of terrestrial gravity upon the atmosphere, is to subject everything upon the surface of the earth to a continuous pressure, which, measured at sea-level, is represented by the weight of a column of mercury 760 mm. (29.9 inches) high,—i.e., in round numbers, fifteen pounds to the square inch.

Two classes of apparatus have been constructed for the utilization of differential pressure. In the one, the air is condensed or rarefied in a receptacle from which the patient inspires, or into which he expires; in the other, the patient is placed within a contrivance in which the air surrounding his body, or a portion of his body, may be condensed or rarefied, while he breathes the ordinary atmosphere. Instruments of both classes were first constructed by Hauke.

We will consider first the most useful class, that in which the patient remains outside the apparatus.

Pressure or rarefaction may be obtained on one of three plans, which may be termed the water-level plan, the gasometer plan, and the bellows plan. The water-level plan depends upon the fact that change of water-level, without entrance or exit of air, in a vessel containing both air and water, will alter the density of the air. This was the principle first adopted by Hauke, and subsequently by Stoerk. Apparatus constructed on this plan simply, are not reliable, and are inconstant. The bellows plan depends upon the fact that a receptacle, with extensible and collapsible walls, may be made by expansion of the cavity to rarefy the contained air, and by contraction to condense it. The lungs work in this manner. The best apparatus for pneumato-therapy constructed on this principle is that of Biedert; one of the simplest and cheapest that of B. Fraenkel. While they are said to have answered admirably, they evidently can easily become fouled if used for expiration, and the pressure does not remain constant. Biedert's is also troublesome to manage. The

principle is simple, however, and means for its employment readily available. Thus, J. Solis-Cohen, in 1866,* used a kitchen bellows to administer inspirations of condensed air, and the same writer in 1880† highly recommended a simple expedient to secure compression, suggested by Dr. W. Y. Gadberry, of Yazoo City, Mississippi,—namely, the employment, after deep inspiration, of an ordinary rubber hand-ball to force an additional quantity of air into the lungs,—as being more useful than drugs in promoting expectoration.

The gasometer plan depends upon the fact that if a vessel open at bottom, and with an opening at top to admit air, which may be closed when desired,—being suspended over water in another vessel, freely communicating with the outer air,—be raised out of the water by a force sufficient to overcome gravity and atmospheric pressure, the air will rush into its interior; that if the cylinder be then closed, the contained air may be rarefied or condensed by adding or subtracting gravity, or its equivalent, to or from atmospheric pressure; and that the positive or negative pressure thus obtained is independent of the volume of air within the air-chamber, which will rise or fall within the water accordingly. Thus we have a ready means of obtaining any desired pressure and of maintaining it, whether we withdraw air by inspiration, or add air by expiration. This is the principle upon which Waldenburg's apparatus is constructed, and upon which depend the modifications of Schnitzler, Weil, Tobold, Finkler and Kochs, and others, all admirable instruments and thoroughly reliable. The best of these are expensive. The minor objections to all instruments of this class are that they are more or less cumbersome, are troublesome to manage, and are not continuously acting, the capacity of the cylinder being of course limited.

This latter objection has been overcome in various ways. Some have so combined two cylinders that one rises while the other falls, and *vice versa*, permitting the patient to use one or the other alternately, with but slight interruption to the process. Geigel and Mayr, whose instrument Oertel commends above all others, have combined a water-level instrument (water-engine bellows) with a gasometer-bell; a series of revolving buckets taking up or discharging a certain quantity

* Op. cit., p. 55.

† Trans. Med. Soc. of Penna., Phila., 1880.

of water to compress or rarefy the contained air, which passes into the bell. This instrument is very costly. The continuous action, which is its great merit, can be secured in a much simpler and cheaper manner, by combining a foot-bellows, such as is used by dentists, with a Waldenburg or other gasometer. This is practically the plan of the instrument which, with the assistance of Mr. Chas. Richardson, I devised in 1883, and which I have already described and exhibited to this society. Originally intended, only to furnish to patients a cheap and safe instrument for home use with compressed air, I have found it capable of modification in other directions; so that when Mr. Richardson has concluded some experiments which he has kindly undertaken to test the feasibility of plans submitted to him, I hope to be able to present to the society an improved instrument, but slightly advanced in cost, which may be used for all the purposes to which the more expensive instruments are applied. Scales and gauges for exact research, may of course be attached to this, as to any other apparatus. To all of the forms of apparatus mentioned, except the simple accordion of Fraenkel, attachments may be added for warming, chilling, drying, moistening, or medicating* the air. Whatever plan be adopted, separate instruments should be used for expiration and inspiration; or two cylinders or bells may be combined in one instrument, as in the "double ventilators" of Waldenburg, Weil, Schnitzler, and Geigel and Mayr. Each patient should have his own mask or mouth-piece.

In order to obtain condensation or rarefaction of the atmosphere surrounding the chest, or the body, of patients unable, or, as in the case of children, unwilling, to undergo treatment by methods requiring their more or less active co-operation, Hauke has devised two forms of apparatus. In one, the chest only is surrounded by an air-tight cuirass, the air between which and the thoracic walls is either condensed or rarefied, the patient respiring the ordinary atmosphere. In the other form, the trunk and limbs enter the apparatus, the face alone being free. A very elegant but more elaborate and expensive means of arriving at the same result, is the pneumatic

cabinet devised by Mr. Ketchum, of Brooklyn, and introduced to the profession by Dr. H. F. Williams of that city. The patient sits in an air-tight cabinet, the air about him being condensed or rarefied, while he respire the ordinary air, which is conducted to his mouth from the outside, by tubing. The respired air is charged with sprays of certain substances.

Were it not for the undemonstrable and misleading claims put forth by the proprietors of this patented instrument, and the questionable propriety of the methods by which it has been placed upon the market, I might pass it with this simple allusion. But since certain claims of historical novelty have misled even so accurate a student as my friend Dr. Platt, of Lakewood, who has completely disproved claims of scientific novelty and unscientific mystery,† I cannot complete this portion of the present article without a plain-spoken denial of these claims. That the instrument is not new in mechanical principle—whatever novelty and merits it may have in mechanical details, from which I have no desire to detract—is proved by the simple reference to the pneumatic chamber of Lange, and the pneumatic cuirass and pneumatic tub of Hauke. That it is not new in therapeutic principle goes almost without saying; for since differentiation of intra-thoracic from extra-thoracic pressure is the sole object, of what moment can it be, whether this differentiation be obtained by raising the one, or by lowering the other? Until those who claim superior virtues for the pneumatic cabinet can prove that the difference between 29 and 30 is either greater or less than the difference between 30 and 31, they will scarcely find general acceptance of their proposition.‡

That the cabinet offers a convenient and elegant method of applying some of the well-known principles of pneumato-therapy, none can deny. Those who prefer it to other and simpler means of accomplishing the same end, are justly entitled to use and express the preference. I simply wish to place on record a flat denial of the assertions that there is any therapeutic novelty about it; or that anything whatever can be done with it, that cannot be done at least equally well, and, in some instances, better, with Waldenburg's, Schnitzler's, or Geigel and Mayr's instrument; or that

* My own usual practice is to pass the air through a Wolff bottle containing a volatile medicament, suspended or dissolved in water, or floating upon the surface of the water. Creasote, terebene, thymol, iodine, benzoin, and similar substances may be thus employed. There are many other ways of medicating the respired air, but this subject is not properly within present limits.

† *N. Y. Medical Journal*, Nov. 6 and 13, 1886.

‡ The questions as to penetration of sprays and vapors are not now under consideration. Dr. Platt's article will elucidate this matter.

the results obtained by its use are any better than those obtained for nearly fifty years in Europe, and for at least ten years in America, with the various methods of pneumotherapy, which I have described this evening.

This will be made clearer as we now pass to the consideration of the mechanical effects of compressed and rarefied air upon circulation and respiration. I say mechanical effects, for these are calculable and measurable with mathematical exactitude. That there must result as well certain other effects, through the nervous system especially, hardly admits of doubt; but the evidence is not perfectly clear and uncontradicted, and the explanation of observed facts is yet involved in obscurity. Not so, however, with the effects due solely to pressure, which follow the same rules as pressure-effects outside the body.*

Let us first review briefly, the well-known mechanism of respiration and of circulation. When by the expansion of the thorax, the contained air is rarefied, the denser outer air tends inward; when the thorax contracts, it compresses the contained air, which tends outward to the now rarer atmosphere. The amount of normal differentiation is small, having been estimated, from observations made in cases of wounds of the trachea, at -1 mm. Hg. during inspiration, and $+2$ to 3 mm. Hg. during expiration. Forced inspiration, however, gives a negative pressure averaging 57 mm. Hg., while forced expiration gives a positive pressure averaging 87 mm. Hg.

The average volume of air which enters or leaves the chest during inspiration or expiration, the *tidal air*, is small, having been estimated at twenty cubic inches; but on forced inspiration this can be increased by one hundred and ten cubic inches of *complemental air*; while forced expiration can expel one hundred cubic inches additional, properly termed the *reserve air*, improperly, the *residual air*; leaving still in the chest one hundred cubic inches of *residual air* or *stationary air*. The term *residual air*, as used in this paper, refers to the latter quantity. The object of this movement of air, is to introduce into the blood O, and to remove from it CO₂. This is accomplished in the alveoli; the air of

which is consequently continually richer in the latter gas, and poorer in the former, than the air of other portions of the lungs; there being by diffusion a gradual increase of one and diminution of the other, until we reach the trachea and larger bronchi, in which the air most nearly corresponds to the outer atmosphere. At each inspiration there is an absolute as well as a percentage gain of O and percentage loss of CO₂; at each expiration there is an absolute loss of both, without percentage change from the end of inspiration, except as effected by the gaseous movement within the alveoli. This movement is in part due to the relatively higher tension of O in the alveolar space, and of CO₂ in the blood, the former passing inward, the latter outward. The volume of O which can be absorbed by the blood is the same at all pressures, but as the weight of a given volume increases with its density, the weight of gas absorbed increases with the pressure. The combination of O with the hæmoglobin, and the liberation of CO₂ from the salts of the plasma, depend largely upon the partial pressure of these gases; association being favored by high partial pressure, dissociation by low partial pressure. Now, both tension and partial pressure, while necessarily depending upon actual pressure, also depend directly upon relative volume, other things being equal. Consequently, whatever tends to increase the relative volume and actual pressure of O in the alveoli, within certain limits, facilitates both its passage into the blood and its association with the hæmoglobin; and whatever tends to diminish the relative volume of CO₂ in the alveoli, within similar limits, facilitates its dissociation from the salts and its escape from the blood.

Whatever increases pulmonary ventilation—that is, the volume of air taken in and expelled during each act of respiration—manifestly increases the pulmonary supply of O, and diminishes the quantity of CO₂; and pulmonary ventilation will be facilitated in one respect by an increase in the negative pressure of inspiration, and in the other, by an increase in the positive pressure of expiration. The weight of O in any given volume of air, and consequently in any given volume of O absorbed into the liquid blood, is of course increased directly as the pressure. Any process that would, while increasing the weight of O absorbed, also increase the rapidity and volume of the pulmonary circulation, would thereby bring a greater number of corpuscles into contact with the greater

* For physiological data and references, see Landois's "Physiology," translated and edited by Stirling. For the physical principles, consult Ganot's or other standard works on "Physics." For elaborate studies, see Waldenburg's and Oertel's works cited. The latter gives full references to investigations up to the date of publication (1882).

number of atoms of O, and thus cause increased oxidation of hæmoglobin.

The elastic tissue of the lungs has a tendency to collapse, which is opposed by the contained air and by the movements of inspiration; creating a condition of elastic tension. The force thus developed has been estimated at 30 mm. Hg. at the end of inspiration, and at 6 mm. Hg. at the end of expiration, or in the dead subject. The elastic traction of the lungs is a principal factor in dilating the auricles when they relax after systole; and the blood-pressure in the auricles being then less than in the *venæ cavæ* and the pulmonary veins, the blood flows into the heart. When the ventricles contract, the pressure within the heart becoming greater than that within the pulmonary artery and the aorta, the blood flows into the pulmonic and aortic systems. As the elastic tension is greatest in inspiration, that movement facilitates distention and filling of the auricles; while at the same time the rarefaction of the intra-thoracic atmosphere, likewise favors dilatation of the heart, and the influx of blood into it and into the *venæ cavæ*. In expiration, the elastic traction ceases to oppose systole, and the compression favors the expulsion of blood from the heart, facilitating likewise the outflow from the aorta and its intra-thoracic branches. Inspiration thus favors circulation, especially through the pulmonic and venous channels; expiration, through the aorta and its subdivisions. An increase in the pressure of the air respired, beyond the limits of ordinary barometric changes, would increase the inspiratory effects due to traction, but somewhat diminish those due to the negative pressure; it would also slightly increase the expiratory effects of pressure, while introducing an increased opposition due to the heightened tension. Diminution of pressure would, of course, have the opposite effect. There is always a slightly less pressure upon the pulmonary veins than upon the pulmonary capillaries, thus permitting the ready inflow of blood through the pulmonary circulation.

We have assumed in this outline study of the relations between respiration and circulation, that the respired air is of the same density as the surrounding atmosphere, and that at the end of inspiration, and at the end of expiration, the pressure within the thorax becomes the same as that upon the periphery of the body; and this is the normal condition. Obviously, if this condition be altered, the circulation will be correspondingly affected. The blood will tend from the point

of high pressure to the point of low pressure,—from the thorax, if the air therein be condensed—towards the thorax, if the contained air be rarefied. In Mueller's experiment, for example, the negative pressure of inspiration is maintained and increased throughout the act. This increases cardiac dilatation; more blood flows into the heart and into the lungs, much less blood is expelled from the left ventricle, so that heart and lungs are engorged and the aortic vessels comparatively empty. The pulse may disappear. The blood-pressure and arterial tension are at first diminished, the arterial tension rising afterwards from vasomotor reaction.

In Valsalva's experiment, there is maintenance and increase of the positive pressure of expiration. The cardiac chambers and thoracic vessels are compressed; no blood can enter the right auricle or *venæ cavæ*; the blood in the lungs rapidly passes into the left heart, thence into the aorta, and out of the chest. The lungs and heart contain little blood, the peripheral vessels are distended, with at first increase of blood-pressure and of arterial tension, which afterwards falls from vasomotor reaction. Notwithstanding the increased pressure, the pulse may be absent from the same cause,—lack of blood in the heart,—to which the absence of the cardiac sounds is attributed.

By the use of apparatus for inhaling compressed air, the negative pressure of inspiration may be converted, as the act proceeds, into a positive pressure—and conversely by making expiration into rarefied air, positive pressure becomes converted into negative. We have then, at first a heightening, afterwards a reversal, of the normal cardiac-respiratory reactions.

One other feature of the respiratory act remains to be noted. One of the forces which the muscles of inspiration have to overcome, and which assists expiration, is atmospheric pressure upon the thoracic walls. The muscular labor of inspiration may be diminished either by invoking the assistance of another force, or by diminishing the resistance to be overcome. The first method is secured by increasing the density of the inspired air over that of the surrounding atmosphere; the second, by diminishing the atmospheric pressure. Reversal of the conditions would impede the act. In a similar manner, expiration may, by pressure-differentiation, be facilitated or impeded.

Having thus fully considered the principal conditions of our problem, we can briefly sum-

marize the observed effects of the therapeutic applications of compressed and rarefied air, with the indications for the employment of these agents.

First, as to the *absolute method*, the method of Tabarie. In this, it is to be remembered, there is a complete change of pressure, the patient respiring air of the same density as that in which he is immersed. The effects of the *compressed air-bath* are due both to the physical changes produced in the air itself by the degree of condensation employed (from one-fifth to three-sevenths of an atmosphere excess pressure, with gradual transitions), and to the increased pressure exercised both upon the interior of the thorax and upon the periphery.

Inspiration becomes easier, expiration being slower and more laborious. As a consequence, the respirations are reduced in frequency and increased in depth, and the mobility of the thorax is increased. These effects continuing after a return to ordinary conditions, the ultimate effect is a gain in vital capacity.

The dilatation of the heart is antagonized, but to a less degree than its contractions are aided; for the normal amount of inspiratory negative differentiation can be brought about by increased muscular effort. Arterial blood-pressure is, upon the whole, lowered, so that the pulse becomes smaller and slower; and the blood tends from the superficies, both respiratory and general, to the deeper parts, and to those vessels contained in cavities with rigid and firm walls. There is increased absorption of oxygen and increased tissue-change, therefore increased nutrition and increased excretion. Upon the nervous system the effects are sedative and soporific. Concerning pathological conditions, both pulmonary and cutaneous, it may be noted that hyperæmia is diminished and absorption of effusions and inflammatory new formations, mechanically favored by compression; exactly as a bandage favors the same results.

The therapeutic indications are found in chronic congestive and inflammatory conditions of the skin, acute and subacute inflammations of the air-passages, chronic bronchitis, pulmonary emphysema unaccompanied by cardiac lesion, bronchial asthma, whooping-cough, pleuritic effusions, and the various forms of pulmonary consumption (in which are included the chronic pneumonias and bronchopneumonias), unless contraindicated by the danger of absorption of septic products present in lungs or bronchi, by high daily fever, by softening or excavation of lung-tissue suf-

ficient to give rise to danger of rupture or of hemorrhage, or by general tuberculosis. Its especial advantage is to prevent extensive lesion in predisposed subjects with incipient disease. It has also been found useful in anæmia and chlorosis, and in obesity. Some observers commend it in certain cardiac lesions; others prohibit it in all. In the absence of personal experience, I can simply express a theoretical leaning towards the more cautious view. Other contraindications are found in states of the brain, spinal cord, or abdominal viscera, in which an increased supply of blood would be prejudicial.

The action of *rarefied air* in the pneumatic chambers is generally likened to the effects produced by ascent of mountains or in balloons, but certain differences exist owing to variation of atmospheric conditions in the higher regions. The rarefied air-bath has not been extensively employed in therapeutics, and as the recommendations made are largely based upon theoretical considerations only, I shall abstain from repeating them.

The *differential method* of pneumato-therapy, is that which is most readily available, most manageable, and, on the whole, most beneficial. Of this I can speak with positiveness, the result of some five years' personal observations. It introduces a new element into our physiological observations,—namely, the possibility of facilitating or impeding the performance of both or either of the phases of respiration, together or alternately. It is, then, particularly applicable in the case of patients too weak to respire properly unaided, or in whom pathological conditions oppose one or the other, or both, of the phases of respiration, or in whom the normal respiratory rhythm has become perverted, whether from excess in one direction or from deficiency in the other. It also produces circulatory effects, due to the difference between intra-thoracic and extra-thoracic pressure,—that is, between the pressure upon the heart, pulmonic vessels, and intra-thoracic systemic veins and arteries on the one hand, and upon the peripheral vessels on the other hand.

Atmospheric pressure upon the surface of the body remaining unchanged, increase of pressure upon the pulmonary surface may be obtained,—1. By inspiration of compressed air. 2. By expiration into compressed air. Decrease of pressure upon the pulmonary surface may be obtained,—1. By inspiration of rarefied air. 2. By expiration into rarefied air.

These procedures may be so combined as to maintain the increase or decrease during

both phases of the respiratory act, or to allow of increase during one phase and decrease during the other. All of these combinations were recognized and described by Waldenburg.

Increased pressure facilitates inspiration and impedes expiration. Decreased pressure facilitates expiration and impedes inspiration.

The facilitation of inspiration or of expiration, or of both, is usually the object of treatment; hence *inspiration of compressed air, expiration into rarefied air*, and the combination of these procedures, are the methods most widely employed. Inspiration of compressed air with expiration into the same medium, which, as pointed out by Dr. Platt, is virtually the method of the pneumatic cabinet, is highly recommended by recent American observers. The effects of these various procedures will vary,—1. With the degree of pressure employed. 2. With the time during which the process is continued; and, therefore, at different periods during its progress. 3. With the amount of voluntary co-operation on the part of the patient. The rationale of these variations being readily understood, and their effect easily deducible from the physiological studies already made, it will only be necessary to give what may be called an average summary under each head. It may first be stated in a general way that the amount of excess or diminished pressure is small,—from one-eightieth to one-thirtieth of an atmosphere; much less than, than in the absolute method. The time varies from ten minutes to half an hour or longer, with interruptions. A period of absolute rest should precede, and another follow, each period of treatment.

Inspiration of Compressed Air.—The excess pressure employed varies from one-eightieth to one-thirtieth of an atmosphere (+ 9.5 to + 25 mm. Hg.). From fifteen to thirty respirations may be made continuously, and the process repeated after a rest of five or ten minutes. The patient, if able, should stand, and, when necessary, the physician may aid inspiration by pressing the shoulders backward, or assist expiration by compressing the chest. When it is desired to localize or locally increase the effect, the healthy side of the chest (*e. g.*) may be strapped, or its motion diminished by manual pressure or pressure against a wall, chair-back, or other suitable object.

The effects, which follow from considerations already detailed, are decrease of muscular exertion necessary for inspiration, dilata-

tion of the alveoli beyond that attainable by voluntary effort; increase in the quantity and in the penetrating power of inspired air,—therefore reopening of air-cells disused from weakness, occluded by the products of secretion and desquamation, or agglutinated from similar causes, and increase in the volume and weight per volume of O brought to and absorbed by the blood; a greater area of blood surface being reached. The subsequent expiration is sometimes slightly retarded, but is deeper, the quantity of air exhaled and of CO₂ eliminated, being increased. Tidal and complementary air are thus increased, reserve air diminished; the first two quantities and a portion of the third quantity, being added to form what is now virtually an increased volume of tidal air, reaching two hundred cubic inches or even more. Diminished frequency of respiration, increased expansion, ventilation, and gaseous exchange, are therefore the immediate effects; increased vital capacity the ultimate and permanent result. The circulatory effects are those of heightened pressure,—namely, an augmented centrifugal tendency of the blood-current; increased force of the ventricular systole; quickening of the pulmonary circulation, bringing more blood, therefore more corpuscles, more hæmoglobin, in proportion to area, into contact with the increased quantity of O; filling of the systemic vessels, with rise of arterial blood-pressure; the pulse becoming at first more rapid, afterwards slower, full, and hard. The blood circulates more actively throughout the body, being richer not only in oxygen, but also in nutritive materials, for pressure upon the diaphragm, transmitted to the abdominal viscera, stimulates absorption of chyme; while heightened pressure and augmented volume of blood in the viscera tend to stimulate functional activity. Thus, increased oxidation and tissue-change stimulate appetite and improve nutrition. Passing to effects upon pathological states,—pulmonary hyperæmia is relieved; inflammatory products are absorbed; cough and expectoration are at first increased, from dislodgment of accumulated materials, afterwards diminished from relief to irritation and diminution of pathological secretions. Increased ingestion and assimilation repair pathological waste, and the increase in weight sometimes exceeds the previous record in good health. Sleep is promoted; night-sweating is often arrested; hæmoptysis is sometimes checked.

Expiration into compressed air impedes the act and requires greater muscular exertion.

If this be sufficient to overcome the obstruction, the amount of air expelled is increased; otherwise it becomes gradually diminished, and the subsequent inspirations are therefore rendered shallower. In other words, tidal air is at first increased, but soon diminished; residual air gradually encroaches upon reserve air, tidal air, and finally upon complemental air; the entire volume becoming practically stationary or residual. The excursions of the diaphragm and thoracic walls become less and less, but at the expense of the contraction, fixed expansion being finally maintained; and if the procedure be pushed to excess with too high a pressure, apnoea may result. Pulmonary ventilation is diminished, and gaseous exchange is retarded; the absorption of O by the hæmoglobin being, however, facilitated, although the excretion of CO₂ is diminished. The effect upon the circulation, is an exaggeration of that produced by inspiration of compressed air, being practically the same as in Valsalva's experiment—depletion of the lungs and heart; over-distention of the systemic vessels, especially the veins. The pulse may disappear from compression of the subclavian artery. Upon pathological conditions, the pressure effects are similar to those already detailed.

Continuous respiration of compressed air, therefore, greatly augments the distention of the thorax and of the lungs, maintaining the patency of the alveoli; and while it diminishes during treatment the volume of air exhaled, the result may nevertheless be properly stated as an increase in vital capacity. The ventilation of the lungs is diminished, but, on the whole, gaseous exchange appears to be slightly increased. There is constantly increasing interference with the dilatation of the heart, and an outward pressure replaces the normal thoracic aspiration of the blood, thus blocking the systemic veins, while at the same time the arteries are distended. Arterial tension, increased at first, soon falls, and the pulse becomes small, slow, and feeble.

Inspiration of rarefied air, which should be conducted against a very small negative pressure, rarely exceeding one-sixtieth of an atmosphere, increases the muscular effort necessary to produce expansion of the chest, and the volume of air needed to supply the proper weight of O. If the requisite effort can be made, there is increase in the elastic tension of the lungs and in the volume of tidal air. If it cannot be made, there is decrease in both these factors. The subsequent contraction of the chest is at first passively facilitated, after-

wards impeded from the resistance of the denser outer air. The muscular effort of this phase is thus also increased, and the frequency of respiration, at first heightened by the excitement of impediment, is finally diminished. Ventilation and gaseous exchange are, on the whole, increased, vital capacity augmented, and the muscles of inspiration strengthened. The blood tends at first to leave the periphery and accumulate within the thorax; but, as there is more blood delivered to the left ventricle, and this can contract with sufficient force to overcome the higher peripheral pressure, the final result is a quickening of the circulation with an increase in the fulness, blood-pressure, and tension of the arteries.

Expiration into rarefied air, conducted with a negative pressure of from one-sixtieth to one-twenty-fourth of an atmosphere, facilitates the contraction of the thorax, exerting a moderate suction-force, and greatly increasing the amount of air expelled from the lungs; thus facilitating the collapse of distended air-vesicles. Subsequent inspirations are rendered easier and deeper; more O-bearing air enters the vesicles; ventilation and gaseous exchange are enormously increased; and the increase in vital capacity is very great. The circulatory effects are similar to those produced by inspiration of rarefied air, but more marked. They vary in different individuals, are evidently different in man and animals, and can be influenced by the manner of subsequent inspiration. While there are conflicting observations as to systemic blood-pressure, there is agreement as to the tendency to pulmonary congestion and the facilitation of cardiac diastole.

The effect of *inspiration of compressed air, with expiration into rarefied air*, is to increase the efficiency of both processes. The alternate expansion and contraction of the lung-tissue stimulates its elasticity. Pulmonary ventilation, both as to interchange of gases and expulsion of effete materials, is vastly augmented. The alternations of opposing circulatory effects relieve hyperæmia wherever present, increase the activity and penetrating power of the blood-current, and stimulate tissue-change and nutrition.

Inspiration of rarefied air, with expiration into compressed air, increases the muscular effort necessary to complete each act, prolongs the respirations, and retards expiration particularly. The alternating centripetal and centrifugal impetus increases the activity of circulation.

Inspiration of rarefied air, with expiration

into the same medium (continuous respiration of rarefied air), increases the muscular effort of inspiration, but hastens and facilitates expiration. The centripetal tendency of the blood is maintained during the entire act, and the heart's action is greatly diminished in force and increased in frequency, the general arterial pressure being much lowered.

THE THERAPY closely follows the physiological indications. The degree of usefulness of pneumatic expedients in any given instance will of course vary with the conditions of the case: and proper hygienic, dietetic, and medicinal measures must also be instituted. In pointing out the classes of cases in which pneumato-therapy is useful, I do not wish to be understood as claiming the method to be competent to cure in every instance.

Inspiration of compressed air, and expiration into rarefied air, are the expedients most generally employed, singly or in combination.

Inspiration of compressed air is of benefit in dyspnoea, of almost any origin; in laryngeal and tracheal stenosis; in chronic bronchitis; in chronic broncho-pneumonitis; in chronic broncho-pneumonitis verging on tuberculosis; in chronic desquamative pneumonitis; in chronic interstitial pneumonitis; in atelectasis; in chronic pleurisy with effusion; in the dry pleurisy of early phthisis; in phthisis at any stage short of general softening, with one or more large cavities, but particularly in the early stages, when deficient respiration, impaired circulation, anæmia, and malnutritive dyspepsia in a predisposed subject, suggest tuberculosis even in the absence of pronounced physical signs.*

The good results of this procedure in phthisis result not alone from the primary effects already alluded to,—the opening of disused or occluded air-cells, with increased vital capacity, increased pulmonary ventilation, increased activity of circulation, absorption of inflammatory products, relief of congestion,—but also secondarily from the increased appetite; relief of cough, with promotion of sleep; and the general stimulus to local and general nutrition, following the systematic pulmonary gymnastics necessitated. In simple anæmia, or chlorosis, without tubercular tendency, the same good effects may be obtained. In asthma,

the inspiration of compressed air is also useful, but high pressures are necessary, and must be cautiously employed. I have succeeded in one case, that of a patient who was attacked in my consulting-room, in cutting short a paroxysm by the employment of a pressure of one-thirtieth of an atmosphere, steadily maintained for nearly fifteen seconds, the expiratory act being held for the time in abeyance. This expedient, which I believe overcomes spasm by a paralyzing effect upon the bronchial muscles, and by inducing fatigue of the diaphragm, was suggested by the experience of Dr. Monell,† who obtained relief in his own person by forced expiration, with his feet braced against the foot-board of his bed, prolonged pause, forced inspiration, pause, and so on. In asthma and emphysema, however, better results are usually obtainable from expiration into rarefied air. In hæmoptysis, good results have been reported from the inspiration of compressed air and its equivalent,—rarefaction of surrounding air in the Brooklyn pneumatic cabinet. Some authors, however, have considered a hemorrhagic tendency as a contraindication to the measure. My own experience leads me to the belief that where there is any weakness of the pulmonary vessels, or any peripheral lesion of hemorrhagic tendency, or where it is inadvisable to increase blood-pressure in the brain, or in the kidneys‡ or other abdominal viscera, the measure is dangerous. In two remarkable instances, elsewhere cited,§ I have, however, been forced to credit it with a tendency to the relief of pulmonary hemorrhage; and this seems to be due directly to the relief of the conditions antecedent to hemorrhage,—namely, pulmonary congestion,—with perhaps an exaggerated stasis at one spot, from mechanical obstructions affecting that portion of the circulatory apparatus chiefly. Inspiration of compressed air is also recommended in mitral insufficiency, and in stenosis and insufficiency of the aortic valves. It is theoretically indicated in dilated heart, and with caution in lipocardiac asthma. I have had no experience with it in any cardiac lesion.

Expiration into rarefied air should be combined with the inspirations of compressed air, where it is desired to increase circulatory activity and gaseous exchange, or to get rid of

* It may be remarked here that evidences of pulmonary impairment, indistinguishable by the ordinary methods of physical exploration of the chest, may sometimes be detected during inhalation of compressed air,—a fact first published, so far as I am aware, by Dr. J. Solis-Cohen. *Vide N. Y. Med. Jour.*, October 18, 1884.

† *N. Y. Med. Record*, August 15, 1866. Cited by J. Solis-Cohen, *op. cit.*

‡ In one of my cases, albuminuria developed during treatment. This may have been merely a coincidence, but at the time I considered it more.

§ *Phila. Med. Times*, February 6, 1886, p. 362.

accumulating and decomposing matters in the interior of the respiratory viscus. *Expiration into compressed air* should be combined with the inspirations of compressed air, when it is desired to relieve congestion, or to stimulate absorption, or when increase of vital capacity is the principal object. Alternation of the combinations may be necessary in some instances.

Expiration into compressed air is recommended in cases of deficient normal expiration, as a means of strengthening the respiratory muscles.

Expiration into rarefied air is of signal advantage in emphysema, and in asthma dependent upon emphysema. It is of some advantage in spasmodic asthma, of less advantage in bronchitic asthma, though of value in all, and in the latter variety may be usefully combined with inspiration of compressed air. *Inspiration of rarefied air* is at times a better combination in emphysema.

Inspiration of rarefied air may also be employed where it is desired to strengthen the muscles of inspiration by increased voluntary exercise, as in cases of contracted thorax in the earlier stages of phthisis, and in convalescence after pleurisy.

That *forced voluntary respiration*, however useful in suitable cases, cannot replace pneumatic treatment by the differential method in cases where the latter is indicated, is evident from the mere statement that it does not produce differential effects; as well as from the fact that many patients are at first incapable of the necessary muscular exertion. As an adjunct or supplement to the differential treatment, or as a means of keeping up the good effects, it often serves excellently.

Pneumato-therapy, steadily growing in favor as the number of physicians resorting to it increases, bids fair to assume at last its proper position among the resources of medical art. It can only be damaged, not benefited, by a tendency to indulge in extravagant claims and reckless assertions. There is nothing mysterious about it,—no miracle, no witchcraft. It has its applications and its limitations, and these are exact and capable of determination, almost with mathematical precision. In practice, the benefits to be derived from it will depend upon its artistic employment,—as the result upon a canvas depends not on the chemical nature of the pigments, but upon the skill with which they are laid on.

As with all other therapeutic devices, including the administration of drugs, the more

clearly we appreciate the pathological conditions present, and the more comprehensive and accurate our knowledge of the powers and limitations of the agent employed, the more skilfully we can adjust the action of the remedy to the requirements of the disease. The first essential, however, is to get rid of the notion that there is anything mysterious in the process, or that it is not governed by the same unalterable laws that affect all other things under the sun, and from which the sun himself is not exempt,—those laws more inexorable than the laws of the Medes and Persians, in that they were not decreed at the whim of man, and cannot be overturned even by rebels against the Legislator.

A CASE OF BASILAR MENINGITIS.

BY W. G. WINNER, M.D., WILMINGTON, DEL.

A. W., the child whose illness I am about to describe, a boy about 3 years of age, was born of healthy parents, and no hereditary tendency to any disease existed, unless it might be that in one of its parents, whose father died of a hemorrhage from the lungs. This boy was the third child in the family, the other two being 4 and 5 years of age respectively, and all of them were nursed from the bottle. The oldest child and this one had been very hearty throughout their entire infancy, but the second child was inclined to be a little delicate. Six months prior to the beginning of the child's present illness he had a furuncular eruption on the face and scalp, which yielded to appropriate treatment, lasting only for a period of about three weeks, and was caused, it was thought, by over-eating, as he was allowed, in addition to the milk, which he still took from the bottle, to partake of the diet prepared for the family, eating heartily of meats and vegetables.

Recovering from this, he enjoyed good health, appeared to be of a rugged constitution, and, with the exception of being slow in learning to talk, seemed to be a bright child for his age, quick to see and to act.

On January 7, 1886, about ten o'clock in the morning, while sitting in his little express-wagon, he suddenly fell over backwards, and was picked up in an unconscious condition, attended with general convulsive movements of the whole body, remaining in this condition for about twenty minutes. On recovering from the convulsion he seemed to be in a dazed and stupid condition, which gradually

wore off during the day, until towards evening, when he appeared to be almost as lively as usual.

The treatment given him for this convulsion was a hot mustard-bath, the inhalation of ammonia, a mustard draught to the stomach, and when he commenced to revive small doses of bromide of potassium were given.

On January 8, in the afternoon, a few minutes after waking from his afternoon nap, he had another attack, similar in character to the first; also one on the 9th, occurring at the same time of day; likewise one on the 11th, 12th, and 15th. A thorough examination had been made to ascertain the cause of these convulsions. The fall from his little express-wagon at the time he had the first convulsion was thought to be merely a result of the convulsive seizure, as it seemed impossible for him to have received any serious injury from a fall of not more than eight or ten inches, and no mark of any kind could be found. After the second convulsion the child was noticed to pick at his nose and to bore into the ear. These symptoms, together with the suddenness of these convulsive attacks, caused a suspicion of the existence of worms as a probable cause of his trouble. One or two thread-worms were found on pressing apart the nates, but neither the injections used nor the medicine given by the mouth caused the expulsion of any worms, or, if any were expelled, they escaped the notice of those who examined the stools. As the child had been placed upon a liquid diet, and the measures used had failed to throw any light upon the case, the bromide of potassium, which had been discontinued after the second convulsion, was again given.

From January 15 to January 20 no convulsion occurred, but on the afternoon of January 20 one occurred, and was followed by two more on the morning of January 21.

By this time other symptoms were manifested, viz., constipation, which was slight at first, was now becoming more marked; there were also light convulsive movements or jerkings, during which the child would throw the hands up to the head, and give a moan or cry as if in severe pain. A slight stiffness of muscles of neck was observed on the 22d, and slight enlargement of the cervical lymphatic glands. The stiffness of the muscles noticed on the 22d became more marked on the 23d.

As these symptoms indicated a trouble of a very serious nature, and rendered the prognosis very unfavorable, a consultation was held with Dr. H. C. Wood. It was then decided to continue the diet of milk, with

light broths, and a little arrow-root starch or tapioca, and to place the child upon a combination of bromides, viz., bromide of potassium, grs. x; bromide of lithium and bromide of sodium, aa grs. v, daily, in divided doses. The iodide of potassium, 5 grains daily, was also given.

On January 23 the child's condition seemed to be getting worse. He was irritable, appetite poor, and the light convulsive attacks were numerous. The temperature, which was normal in the morning, showed an elevation in the evening of about one degree and a half, and a correspondingly quickened pulse-rate.

On the 24th a blister was placed on the back of neck, his appetite was a little better, and he rested fairly well at night, the temperature being but slightly elevated. An expression of dulness, which had developed about the 20th, was to-day very marked, and the muscles of neck more rigid.

Blistered back of left ear on the 26th, and as symptoms of bromism existed, the amount of bromides taken daily was reduced one-half. No evening elevation of temperature to-day, but light convulsive movements numerous in the forenoon, and occurring occasionally in the afternoon. The child is still peevish, but takes food a little better.

January 28.—No severe convulsion has occurred since January 21 until to-day, when two convulsions took place, and the light attacks are numerous.

January 30.—Increased the combination of bromides to full strength, and continued the same until bromism was again developed. A blister was placed back of right ear.

January 31.—The appetite not quite so good to-day, probably an effect of the bromides. The bowels have been kept open so far during his sickness by enema mainly, but sometimes by medicine given by the mouth. Gave four $\frac{1}{4}$ -gr. doses of calomel to-day, repeating the same on February 1, when the bowels moved three times. The temperature on the evening of February 1 was 100.8°, late in the evening, this being the first elevation noticed for several days.

On February 2 the bowels moved three times again; no calomel given since the morning before; the light attacks not quite so numerous as on the 1st, but glands of neck becoming still more enlarged. Bromide mixture reduced down to one-quarter strength, but continued the iodide as usual.

February 3.—Light attacks not so numerous as yesterday; appetite poor; bowels

moved three times again. In the afternoon he awoke from a sleep of about three hours with considerable dulness, and in about twenty minutes had a convulsion, lasting for two or three minutes. As I have not described any of these convulsions, I will do so in regard to this one, as I had an opportunity of witnessing it. It commenced with a twitching of the hands and a falling forward of the head. At the same time the arms were thrown upward towards the head, eyeballs turned upward, and a rapid moving of the jaws occurring, followed by partial opisthotonos, and recovering from the convulsion with a gasping and a yawning, and then a cry as if from fright. At no time in any of his convulsions was any frothing of the mouth observed, nor was the tongue bitten. These severe convulsions generally lasted for several minutes, the first one that he had being about the longest one in duration, viz., about twenty minutes.

February 4.—Ceased giving the bromides to-day, as there did not seem to be any benefit arising from their use. Another convulsion to-day, but not quite so severe as the one yesterday. Gave three $\frac{1}{4}$ -gr. doses of calomel to-day.

February 5.—Bowels moved twice to-day. Appetite seems to be improving since suspension of bromides.

February 6.—Blistered back of neck. Child seems a little brighter to-day.

February 8.—No change since the 6th in his condition. Gave four $\frac{1}{4}$ -gr. doses of calomel to-day.

February 9.—Another convulsion occurred, but not quite so severe as the last one.

February 11.—Blistered back of right ear.

February 14.—Not quite so well to-day as he has been; light attacks (convulsive) more numerous.

February 17.—Light convulsive attacks not quite so numerous. Bowels moved by giving two $\frac{1}{4}$ -gr. doses of calomel. A blister was placed back of right ear.

February 18.—Light attacks not so numerous, but for the last four days he cannot control the passing of water. Appetite during this period seems better. Gave four $\frac{1}{4}$ -gr. doses of calomel, but bowels moved only after an injection had been given late at night.

February 19.—Slight symptoms of salivation presented, but otherwise he remains about the same. The light or momentary convulsions, which have been occurring every day for several weeks, ceased to-day about noon, but their cessation was preceded by a convulsion of four or five minutes' duration.

February 21.—A blister was placed back of left ear.

February 25.—No light attacks have occurred since the 20th. Bowels, although very constipated, have moved naturally for the last three days. Blistered back of right ear. Commenced giving cod-liver oil to-day, and anointing the enlarged glands with an ointment, viz., ungt. belladonnæ, ungt. hydrarg., equal parts.

February 27.—Light attacks commenced again to-day, and in the evening he had four convulsions.

February 28.—Blistered back of neck.

March 2.—Another convulsion to-day. Bowels still constipated, but moving naturally. A little blood has been noticed on fæces for several days. This appears to be hemorrhoidal in character, and is probably due to the constipation.

March 4.—During the night had three convulsions. Have run the amount of iodide up to 12 grs. per day.

March 8.—Three convulsions in the morning. Iodide has been gradually increased until 30 grs. per day are taken, and symptoms of iodism developed.

March 9.—Dropped iodide to 16 grs. per day.

March 13.—A convulsion occurred in the morning; light attacks very numerous; he also has the hiccoughs.

March 23.—The hiccoughs, although severe for several days, have ceased; one convulsion to-day.

March 27.—Two convulsions.

April 16.—For the last two or three weeks light attacks occur almost constantly during the day. The child cannot walk nor stand alone; cannot feed himself. The dull expression about the eyes is now very marked, and his appearance is one of helplessness. The boy has been losing flesh very rapidly.

April 19.—Two convulsions to-day. After they had occurred he has better use of his limbs, being able to stand alone.

May 15.—A convulsion during sleep, and the first one noticed to occur while sleeping. The light attacks do not now occur. Muscles of neck are not quite so rigid, and the glands are lessening in size.

From May 15 the patient has gradually improved. No convulsions have occurred up to the date of writing this article (November 13, 1886). The stiffness of muscles of back of neck still exists to a slight extent. The lymphatic glands are also a little enlarged, but both the stiffness of muscles and enlarge-

ment of glands are still subsiding. He has improved in his speech, eats heartily, and is quite active upon his feet. He has gained considerable in weight, and seems almost as well as previous to his severe illness. The number of severe convulsions which the child had is about thirty-five, and these were from one to twenty minutes in duration.

*GALVANISM AND BROMIDE OF QUININE
IN THE TREATMENT OF CHRONIC
CATARRH OF THE MIDDLE EAR.*

By J. A. PATTERSON, M.D., SALEM, N. J.

CHRONIC catarrh of the middle ear and its usual attendant, tinnitus, is a disease whose treatment has never been very satisfactory.

In the great forward strides made in both therapeutics and surgery at the present day the treatment of this affection has made comparatively very little advance, therefore I offer these remarks, crude as I know they are, hoping they may be of some value towards the more successful relief of tinnitus aurium and progressive loss of hearing.

I have many times been struck by the similarity of cinchonism and the symptoms of catarrhal deafness, and reasoned that quinine must have some specific action upon the middle ear, for we know where cinchonism has been kept up in a patient for a lengthy period a chronic congestion of the middle ear is often produced, leaving impairment of hearing in greater or less degree, and often tinnitus.

Reasoning from analogy, I determined to try the effect of quinine in small doses in such cases, but in two instances in which I used the sulphate my patients derived no benefit. Now, it is a well-known fact that bromine in its various combinations, as bromide of potassium, sodium, etc., controls and lessens the blood-supply to the cranium, and will often mitigate somewhat the roaring which these patients experience in their diseased ears, so I thought that probably a combination of bromine and quinine would act better. Accordingly I procured some bromide of quinine. The first patient upon whom I tried it was a lady with history as follows:

Right ear: abscess three weeks ago; drum membrane shows pin-point perforations, opening valve-like upon inflation of the middle ear; watch heard at four inches. Left ear: hearing *nil* from purulent catarrh, which followed scarlet-fever in childhood, and existed

up to the age of thirteen years. Deafness and tinnitus in both ears,—in left ear for a number of years, in right ear progressing for the past six or eight months. She consulted me very irregularly for several months, and was somewhat improved by galvanism applied directly to the ear, one electrode, moistened with a saline solution, being introduced into the external auditory meatus, and various remedies. Upon May 20 I put her upon grain-doses of bromide of quinine t. i. d. In three days she returned, saying she had used the medicine faithfully, but it increased the tinnitus so much she had to abandon it, since which time it has decreased to its usual intensity. She frankly stated she believed I had given her quinine, as she readily detected its usual effects upon her, and as I compounded the recipe in person, I knew she had no opportunity of reading the prescription. I then gave the drug in $\frac{1}{4}$ -gr. doses t. i. d., with slight improvement. June 10 I began giving it in $\frac{1}{10}$ -gr. doses four times a day, still continuing the use of galvanism, when the hearing began gradually to improve, until it reached in right ear nine inches for watch; tinnitus *greatly* improved. She has now stopped treatment, saying she hears well enough, and the tinnitus is so slight as to cause no annoyance.

The second case. Mrs. —, æt. 55, came to me for deafness of many years' duration and intolerable tinnitus of over a year's duration. There was found to be a large perforation in the membrani tympani of each ear, following aural discharges in very early childhood. Watch could not be heard at contact in either ear. Under three months' treatment, by weekly applications of the galvanic current, and quinine bromide $\frac{1}{10}$ gr., four times a day, there has been a gradual improvement in hearing, first by hearing the watch at contact, and on last consultation she reported having heard the entire sermon at church, sitting in her accustomed pew, the same clergyman as usual occupying the pulpit; the first sermon she had thus enjoyed for some years. The tinnitus has greatly and decidedly improved, and from being very despondent she is in much more cheerful spirits owing to its decrease. She is now out of town on a prolonged visit, therefore I have for the time lost trace of the case.

Other cases in which I had begun giving this remedy have failed to report themselves, consequently no data can be thus obtained.

In conclusion, I would say that systematic, prolonged use of galvanism, combined with systemic treatment, will do more for the relief

and cure of chronic catarrh of the middle ear than any mode of treatment I have yet tried (attention to the health of the nasal and pharyngeal mucous membrane, of course, never to be overlooked or neglected). It is necessary that the physician should know that the results are often slow and gradual, although in some instances very rapid results are obtained, as the following case will show :

A. C. K., æt. 56, consulted me November 17 for tinnitus and deafness in left ear for past ten months, gradually increasing. Politzer's inflation shows Eustachian tubes patulous, although there exists a chronic rhinitis. Membrana tympani intact and of dusky hue. I prescribed an alkaline wash for the nose, and applied galvanism.

November 23.—Since last consultation no tinnitus, and hears better.

December 7.—Hearing improving ; momentary returns of the tinnitus noticed ; same treatment.

December 29.—Been entirely free of tinnitus for two weeks, which is the longest freedom he has had for nearly a year. Hearing greatly increased, so as to be now, he thinks, normal. He then discontinued treatment.

I close, hoping to be able to report continued good results from the bromide of quinine treatment.

213 BROADWAY, December, 1886.

THE THERAPEUTIC INDICATIONS IN DIFFERENT TEMPERAMENTS.

By W. G. KEMPER, M.D., OMAHA, MO.

THE recognition of the temperament of a patient is in many cases nearly as important as the diagnosis of the disease. It would be better understood why maladies in a given family have certain peculiar features and tendencies, and the treatment, as well as the prognosis, would be simplified if the subject was always taken into consideration.

The physician who, by long practice and careful observation, has acquired a knowledge of the peculiarities of his patients, is said to "know their constitution," and is, therefore, trusted to a greater degree, and deservedly so, for his methods are more scientific and successful than the practice of many who apply routine remedies to the same disease without taking the temperament into consideration. Idiosyncrasies and the unusual action of drugs, instead of surprising us, should be expected.

In olden times temperaments were supposed to be due to the relative presence of *fire, water, air, and earth*, and were divided as follows: "The *choleric* where the warmth, the *phlegmatic* where the moisture, the *sanguine* where the air, and the *melancholic* where the earth has the upper hand."* But it is now understood that the temperaments are due to the relative development and energy of the nervous, muscular, lymphatic, or circulatory system.

The words constitution, diathesis, and cachexia are sometimes misused for temperament. *Constitution* refers to the state of health, or the power to resist disease; *diathesis*, a tendency to certain diseased conditions; and *cachexia*, the actual presence of a certain diseased state.

The NERVOUS (*Mental*) temperament, depending upon the predominance of the nervous system, is characterized by a comparatively large head and small body; a long face, with a high forehead; the bones and muscles small but well formed; chest and shoulders narrow; the complexion is usually light, but may be dark; the skin delicate, generally moist, but rough when dry; the hair fine, soft, dry, and not abundant; the teeth small and separated; nutrition is imperfect; the appetite poor; stomach and viscera small; not much adipose tissue. Urine is abundant, containing alkaline phosphates; the fecal discharges small. The pulse is small, hard, and quick; the movements quick and active. There is great activity of the mind, a lively imagination, an excellent memory. Great sensitiveness to pain, and but little power to resist disease or starvation. Often displays idiosyncrasies, and is therefore difficult to treat. The diseases are usually due to overwork. In many cases a tendency to insanity, neuralgia, and other nervous affections is present. In low fevers there is apt to be great restlessness, delirium, and much wasting. In the treatment, rest, nourishment, tonics, and sedatives are indicated.

The MOTIVE (*Bilious, Choleric, Melancholic*) temperament, depending upon the predominance of muscular system and its "supply depot," the liver, is distinguished by a long angular figure, with firm, rather full, muscles; the face narrow, of dark, sometimes sallow, complexion; hair and eyes dark; the skin dense; nails hard and of slow growth; the teeth large; stomach and viscera small; pulse hard and slow; disposition harsh and stern,

* Lavater.

often sad ; nervous system in good condition, but prefers physical to mental labor ; but little tissue-change takes place, hence little food is required ; great power of endurance to pain, starvation, or disease. Biliousness and malaria are the most common diseases in this temperament. Purgatives are usually indicated. In low fevers the prognosis is good, as there is but little waste.

When this temperament is blended with the nervous, we are apt to find a small figure, with a dark complexion, whose movements and actions, though generally slow, are quick, active, and passionate when aroused. When blended with the sanguine, the nervous system being poorly developed, we have the immense bones and muscles and comparatively small head of the prize-fighter.

The **SANGUINE** (*Vital*) temperament, depending upon the predominance of the circulatory system, is recognized by the broad, rotund figure ; full chest ; muscles firm and well developed ; face round and florid ; hair and eyes light ; skin smooth and fair ; the nails pink and soft ; the teeth even and undecayed ; abdomen well developed, and the digestive powers perfect ; disposition pleasant and cheerful ; nervous system in good order ; blood-making powers strong ; the actions and movements strong and graceful ; pulse strong and frequent. The urine is of high specific gravity ; the fecal discharges small. There is great resistance to disease, but when affected it takes an active, rapid course. Inflammation, gout, rheumatism, and allied disorders are most frequent ; and the remedies indicated are blood-letting, sedatives, alkaline salines. In low fevers the prognosis is unfavorable, on account of the high fever, but the crisis once passed will rapidly recuperate.

As age advances this temperament often becomes blended with the following :

The **LYMPHATIC** (*Phlegmatic*) temperament, depending upon the preponderance of the lymphatic system, is characterized by the large, bulky body ; broad shoulders ; bones large ; muscles large and flabby ; short, fat neck ; round, pale face ; light hair and eyes ; skin dense ; nails large and brittle ; teeth large ; abdomen large ; great amount of food required ; nervous system not well developed ; mind not active, but the memory good ; moves about slowly and indolently ; circulation slow ; pulse slow and soft ; dilatation of the heart ; constipation, diarrhoea, piles, and other bowel complaints are the most frequent diseases. Inflammations are not usually severe, but are apt to become chronic. Fevers seldom high.

Purgatives, stimulants, and heart tonics are indicated. In low fevers the prognosis is bad, and convalescence extremely slow, requiring plenty of food, stimulants, and tonics.

Polysarcia usually comes on after middle age, which may be prevented by exercise, nitrogeous food, and but few liquids, especially during meal-time.

Where all the temperaments are blended we would expect to find a perfect constitution, that, like the *wonderful one-hoss shay*, would *wear out*, but never *break down*.

*APOCYNUM CANNABINUM IN DROPSY.**

By J. A. LEWIS, M.D., ITHACA, N. Y.

IN reply to the query of Dr. Peters I have to report the history of a few cases of pleurisy with effusion treated with apocynum cannabinum. I prefer to give those cases that fell in my hands after the effusion was well marked.

CASE I.—J. C., aged 13, male, January 15, 1885. Was taken sick January 7 with initiatory chill, followed by high fever, cough, and rapid respiration ; effusion well marked ; level of fluid at fourth rib. Treatment : fl. ext. apocynum cannabinum, \mathfrak{z} i. Five drops every three hours.

January 19.—Feels better ; fluid disappearing ; at level fifth rib.

January 29.—Fluid entirely gone ; appetite good ; temperature and pulse normal ; discharged.

CASE II.—January 24, 1886. George P., aged 18 ; barber ; taken sick with pain, fever, and rapid respiration.

January 1.—Confined to bed two weeks ; improved, and was able to walk out ; had been treated for intercostal neuralgia. Physical examination revealed the fact that his left pleural cavity was entirely filled with fluid ; was given fl. ext. apocynum cannabinum 20 drops every four hours ; free catharsis took place after the fourth dose ; drug diminished to 10 drops every four hours ; rapid recovery took place, with complete expansion of lung and normal respiration February 15.

CASE III.—March 28, 1886. John C., aged 14 ; waiter-boy on railroad. After violent exercise, February 10, 1886, was taken with chill, followed by fever, cough, slight pain in side. Nothing was done for him

* Read before the Materia Medica Section of the New York Academy of Medicine.

until he came to me, March 28; right pleural cavity nearly filled with fluid. Treatment: fl. ext. apocynum cannabinum. Ten drops every four hours were given. Lived six miles from me, so did not see him again until June, when I met him by accident. His story was that he got well in a week, and went to work May 3, 1886.

CASE IV.—Mrs. P., aged 43. History of latent pleurisy of four weeks' standing of left chest; complete flatness on percussion; heart to right of sternum; no vesicular murmur in lung. Change of position did not alter the physical signs. Advised aspiration, which she would not consent to until drugs had been tried. Treatment: fl. ext. apocynum cannabinum, gtt. xv; potassæ iodidi, gr. viii, per dose every four hours.

May 5.—Feels a little better; treatment continued, and by May 18 all fluid had disappeared, and she has remained well since.

CASE V.—Susie G., aged 23; shop-girl. History of latent pleurisy; right chest filled with fluid to fourth rib; has been treated for intercostal neuralgia. Treatment: fl. ext. apocynum cannabinum, gtt. x, every four hours. Fluid rapidly disappeared, and she remained well until December, when I was called by Dr. Winslow to see her at his office. She then had aphonia from ulceration of the vocal cords, which is undoubtedly laryngeal phthisis. There was no fluid in the chest. He has since lost track of her.

CASE VI.—Harris B., aged 3, son of Dr. Beckwith, of Ithaca. Taken sick July 10; chills, fever, slight cough, and pain in abdomen. Was asked by the doctor to see him July 18, when we found right chest nearly filled with fluid. Advised fl. ext. apocynum cannabinum, gtt. ii, every two hours, until free catharsis took place, then to diminish to 1 drop. The fluid entirely disappeared in fourteen days. He has since remained well.

CASE VII.—Grace C., aged 4 years. History of acute pleurisy, commencing November 10; right chest filled with fluid. Treatment: fl. ext. apocynum cannabinum, gtt. iv, every four hours; complete recovery in fifteen days.

MULTIPLE ABSCESS OF THE LIVER.

By J. A. BACH, M.D., MILWAUKEE.

ALTHOUGH by most surgeons the early evacuation of an abscess is considered a surgical axiom, it has many times occurred to me why non-interference in abscess of the

liver is so generally advised. Even with our present knowledge of antiseptic surgery our authors are extremely cautious, and seem to be fearful of bad consequences in the event of free opening and drainage of abscess of the liver.

During the last few weeks I had occasion to meet with a very remarkable case of multiple abscesses of the liver, resulting from pyæmia, the treatment and the results of which might be of interest. The history of the case is briefly this:

Albert Schuette, æt. 9, residing at 302 Twenty-fourth Street, while playing about the school-house, fell and struck upon his left hip, while another little boy fell upon him, striking his body at about the region of the liver. The next day he complained of pain in his left thigh, and also of difficulty of breathing, probably from a slight pleurisy. The parents of the little boy, thinking this only transient, did not pay any attention to it until about the tenth day, when I was called. Upon examination I discovered a large abscess on the left thigh, which seemed to involve the periosteum of the femur. I also discovered a great enlargement of the liver, in the region of which the boy felt a good deal of pain. At this time that peculiar pasty, jaundiced, and exhausted appearance was quite prominent. Temperature 103°, pulse 128. The abscess on his thigh was freely laid open, and discharged from four to five ounces of pus. The after-treatment with carbolic acid washes, etc., soon effected a complete cure of this, but the temperature still remained high. I directed hot fomentations over the liver, and in a few days, upon re-examination of this region, the liver was still much enlarged and quite sensitive. In the lower region of both the right and left lobes of the liver I now discovered two tumors, each about the size of a goose's egg. The tumors being rather deep-seated, I could not clearly detect fluctuation, but verified the presence of matter therein by the introduction of the hypodermic needle, with which I withdrew about five grains of pus. I now directed poultices of linseed, and after a few days the tumor of the right lobe could be much more clearly felt, as it began to point outwardly. Fluctuation could now be felt, and as the case was quite urgent, temperature 103½°, pulse 130, and the boy was rapidly losing strength, I decided, without waiting for any further developments, to freely lay open the abscess, and accordingly the next day, with the assistance of Dr. Frank, this was

done. A careful incision of about two inches in length, and extending down into the cavity of the abscess, gave vent to about four ounces of thick, greenish pus. As this discharged, care was taken not to allow any to leak into the peritoneal cavity. After evacuation of the abscess, a horseshoe rubber drainage-tube was introduced, through which the cavity was carefully washed out every day with carbolic acid solution. After three days the abscess of the left lobe was treated likewise. Of course, before as well as after the operation, antiseptic precautions were taken. The boy made a perfect recovery.

48 JUNEAU AVENUE.

*PERMANGANATE OF POTASSIUM IN AMENORRHŒA.**

BY DR. H. I. BOLDTS, NEW YORK.

IN view of the interest and importance of Dr. Billington's paper, and the discussion which it has evoked, I have looked over my records, and report the results and the conclusions at which I have arrived.

I have been able to follow forty-three cases, and find that in the class of robust persons who have recently made a sea-voyage, have then menstruated scantily, or missed altogether two or three times, that the permanganate of potassium, given in 1-grain doses three times daily, after meals, up to within one week of the expected catamenia, then the dose to be increased to 2 grains three times daily, it has been effectual and permanent in each instance, the number of cases of this class being fifteen.

Out of seventeen patients who were anæmic or chlorotic, only two patients derived benefit from the permanganate of potassium treatment employed alone; one of these, a chlorotic, at her next epoch, she having missed four months entirely, and the two preceding periods being very scanty, the flow lasting only a few hours, had such profuse flow that I felt it necessary to give ergot. The remaining fifteen patients derived benefit, more or less, only by general tonic treatment, viz., hygienic, dietetic, and medicinal.

The next class of patients, eleven in number, were well nourished, some plethoric, and no particular cause could be found for the amenorrhœa. In seven of these the remedy produced the desired effect one time only, in

three for two months, and in one for three periods; after that the drug had no effect. In three of the first seven cases the epoch was established again regularly and normally, without any more cause than could be found for the origin of the complaint.

My conclusions, then, are: That in such as the first class of patients cited, the permanganate of potassium is "the" remedy. In the second class, it is of service only when employed in connection with such treatment as would have a tendency to overcome or help the cause of the amenorrhœa; and in the third class the results are very variable, failures being, in my experience, the preponderance.

With the binocide of manganese my experience has been too limited to speak. The administration of the remedy has given the best satisfaction in my hands when the crystals are put up in ordinary gelatin-capsules, one capsule to be taken after eating, followed by a glass of milk or soda-water. The gastric disturbance has then been usually very little or none; but four patients out of the total number of forty-three have had much cause to complain. The number of patients for whom the remedy has been prescribed has been considerably larger; but, as we all know in public practice, it is very difficult to keep patients under observation, as is also the case with many private cases. The mentioned number, however, have been successfully observed by me. Dr. Billings, I believe, mentioned the usefulness of the potassium salt also in menorrhagia. I have tried it also in this condition a few times, but with total failure. The *hydrastis canadensis* has given fair satisfaction for this complaint in my hands. Lately, the latter drug has also been recommended by Mendes de Leon in this and other pathological conditions of the female organs of generation, such as dysmenorrhœa resulting from displacement of the uterus, and chronic pelvic cellulitis.

411 SIXTH STREET.

PILOCARPINE IN RHEUMATIC TETANUS.

BRÜNAUER treated a case of tetanus of rheumatic origin, where the slightest irritant produced violent spasms, with subcutaneous injections of pilocarpine, 2 centigrammes in each dose. Other modes of treatment tried during five days had failed. The injections, with use of the chloral at night, resulted in recovery after an illness of two weeks.—*Deutsche Medicinal Zeitung*, No. 61, 1886.

CEREBRAL PNEUMONIA.

IT is but a trite saying that in pneumonia the cerebral symptoms may be so severe as to mask the lung-disease, but as the time of year is upon us when cases of this character are especially apt to occur, we feel justified in calling attention afresh to the subject.

In old people, and especially in drunkards, delirium may be so violent as to call attention away from the pulmonic symptoms, which, indeed, may be so slight as not to be perceptible at all, except in that counting the respirations will usually show a marked acceleration of the breathing rate.

In children the evidences of the symptoms of a cerebral inflammation may appear to be complete. Headache, constipation, great prostration, fever, delirium, convulsions, opisthotonos, and strabismus may unite to form a picture of an attack of cerebro-spinal meningitis so close to reality that even a careful, well-informed practitioner may be misled. In some cases there is a peculiar cry like that of meningitis. If, under these circumstances, the cough be suppressed, suspicion may not be at all aroused. Moreover, even if the practitioner be wide awake, the physical signs of pneu-

monia may be so masked as scarcely to be discoverable. Grisolle, as quoted by Prof. Alfred L. Loomis, affirms that in a majority of cases of senile pneumonia exploration of the thoracic organs gives negative results. We think that this statement is not absolutely correct. We have seen a number of cases in which the crepitant râle was entirely absent, some in which even bronchial breathing was suppressed, and others in which the only physical signs were an absence of true respiratory murmur and dulness on percussion. It is possible that a transmitted respiratory murmur may in some cases be heard, but we can scarcely conceive that distinct percussion dulness can be absent in pneumonia of the adult.

In young children the pulmonic physical signs may be exceedingly obscure. Some years since it was our duty to perform an autopsy upon a child who had been attended by the late Dr. John F. Meigs and another practitioner whose name we omit, as its possessor is still living. The child was the son of a leading merchant, was attended with the utmost care by these two gentlemen, who would at the time have been acknowledged to be the leading practitioners of Philadelphia. Nevertheless, after the baby had been treated for nearly two weeks for pneumonia of the right lung, the autopsy showed that the right lung was nearly normal, only secondarily congested, whilst a pint of purulent effusion filled up the left chest cavity. Quite recently we saw a case in a child three years of age in which the symptoms were high fever, convulsions, strabismus, fixed rigidity of the neck, with, on the third day of the disease, collapse, from which a reaction was with great difficulty obtained. The most careful examination by Professor Da Costa and ourselves, on the third day of the disease, revealed only slight relative dulness over the posterior portion of the right lung. No change was perceptible on auscultation, and even the percussion note was distinctly tympanitic, only a little less so than that of the opposite side. After death, which took place on the sixth day, pneumonia was found, with intense congestion of the brain and of the pia mater, but no fibrinous or purulent exudation at all about the brain. There was much more serous fluid in the brain than should have been, but microscopic examination failed to detect any outwandering of corpuscles from the vessels or any pus-corpuscles.

The matter is made still more difficult by the fact that meningitis may develop in pneumonia. It probably is not possible to say

with certainty in a case of pneumonia, whether the meningeal symptoms are the outcome of a true meningitis or simply of a meningeal irritation. The practical fact, however, in these cases is that the pneumonia is the important primary affection, against which in chief part treatment must be directed. When the physical signs are very much masked, aid in the diagnosis can be often obtained from the symptoms themselves. Thus, especially in children, the temperature is much higher in cerebral pneumonia than in simple meningitis. In the case which has already been detailed the temperature, although checked by the free use of antipyrin, and repeated applications of cold to the head and body, several times reached 106.8° , and would, we believe, if it had not been interfered with, have gone to a point at which it would have killed the child by thermic fever.

The importance of the temperature is enhanced by noticing that it is out of proportion to the intensity of the meningeal symptoms. Thus, in our case, on the fifth and sixth days of the disease the meningeal symptoms were less marked than they were on the fourth day; the neck was not quite as stiff, there was no increase of stupor, the strabismus was less, rather than greater than it had been, and no convulsions occurred after the beginning of the second day. Fulminating sthenic meningitis is an excessively rare disease in children; although it is elaborately described by writers, we are sometimes tempted to doubt its existence, and to believe that the cases in which the diagnosis has been confirmed by the autopsy were really instances of the constitutional affection in cerebro-spinal meningitis, or were examples of imperfect autopsies at which the attention has been drawn away by the secondary affection from some original lesion.

THE TREATMENT OF WHITLOW.

FROM time immemorial the treatment of whitlow has consisted in the early performance of deep incisions carried down to the bone and prolonged poulticing. This routine treatment is in the main accepted by most surgeons, yet great varieties of opinion are held as to the time when incision should be performed, the locality, and the duration of poulticing, it being held by many that the necrosis that so often follows this affection is due to the prolonged heat from the poultice

as much as to the disease itself. The subject recently has been attracting considerable attention, and Mr. Allingham (*Medical Press*, September 29, 1886) shows that there are several varieties of whitlow, and each of these requires a special mode of treatment. Mr. Allingham described five varieties of whitlow. The first, which he terms phlyzacious pustule, is nothing more than an accumulation of fluid between the epidermis and true skin. Of course, all that is required is to puncture the blister and let out the fluid. In another form, a collection of pus may form under the nail, as a result of a puncture or a breaking down of blood, following a pinch, and may give rise to considerable pain of a throbbing character. In the treatment of this class of the disease, Mr. Allingham recommends the insertion of a hare-lip pin, or some such narrow-bladed instrument, beneath the nail, keeping it quite close, so as not to wound, if possible, the tissue beneath, passing it down to the collection of pus, and then depressing the needle, and then allowing the pus to flow out. This gives instant relief, and prevents the matter from burrowing beneath the nail, and so separating it from its bed. Poulticing and waiting for the pus to work itself to the surface will entail a needless amount of unnecessary suffering upon the patient. Another form of treatment, which may be employed when the collection of pus is situated at the root of the nail, is to cut away the nail from the seat of the inflammation.

Under the term cellular whitlow, Mr. Allingham describes the inflammation of the cellular tissue covering the terminal phalanx, where the bone is free from periosteum. Inflammation of this locality, by producing strangulation of the vessels, cuts off the supply of blood to the part, and as a result causes necrosis of the phalanx. Almost as soon as the first symptoms of this affection develop, as may be recognized by acute pain in the part, with the tip of the finger swollen, tender, tense, and sometimes red, a free incision should be carried directly down to the bone, and necrosis of the terminal phalanx will thus often be prevented. When cases come under observation in which necrosis of the phalanx has already taken place, deformity may be prevented, according to Mr. Allingham, by making an incision along the palmar surface of the finger, removing the necrosed bone, and placing a narrow splint on the back of the finger, allowing it to project half an inch beyond the nail. The nail should then be fastened to the splint by adhesive plaster, so as to prevent it curling

up, and it thus may act as a background on which new bone may develop.

The fourth form of whitlow described is an inflammation in the sheath of the tendons over the first or second phalanx. It may arise from inflammation spreading from without, or by a purulent inflammation of the synovial sheath of the flexor tendon. The great dangers arising from this form of whitlow are that the tendons may be destroyed, the inflammation extend into the joints, or the pus find its way into the palm of the hand. The finger in this affection soon becomes swollen and flexed, and is the seat of severe throbbing pain, the part is hot, and in the latter stages deep-seated fluctuation may be recognized. If this is allowed to progress, the whole finger may become involved, so as to present two swellings separated by a constriction corresponding to the joint.

The treatment of this affection is identical, according to Mr. Allingham, with that of periosteal whitlow, from which, in fact, the tendinous inflammation can only be recognized with very great difficulty. Mr. Allingham is strongly in favor of treating these affections by lateral incisions, for on account of the difficulty of recognition of the locality of inflammation, should the inflammation be confined to the periosteum, the central incision must be carried through the tendons to reach the bone, of course unnecessarily damaging the tendon. Mr. Allingham, therefore, recommends the lateral incision, claiming for it the following advantages :

First.—As it is difficult to tell whether the whitlow is periosteal or tendinous, by the lateral incision, if it should be periosteal, no damage is done to the tendons by cutting through them.

Second.—By lateral incision the tendons cannot prolapse from their sheaths, and therefore the liability to gangrene is diminished.

Third.—After this method of treatment the finger can be flexed, and so relax all the structures and relieve pain, whereas by the central incision the finger should be kept straight, to prevent the tendons slipping out of their sheaths ; at the same time straightening such inflamed part greatly increases the pain.

Fourth.—If the incisions are on the side they are less likely to be pressed upon, for the cicatrix may become tender, which, if in the centre of the hand, is exposed to pressure every time the hand is closed. Again, a cicatrix in the middle line may contract, and cause the finger to become permanently

flexed, whereas, if the incisions are at the side, such a result could not take place.

So much for the most recent opinions as to the surgical treatment of whitlow, a mode of procedure which is unavoidable when pus has collected.

The less severe forms of furuncular inflammation may be aborted in many cases, according to Dr. Weiss (*Medical Record*, November 27, 1886), by the inoculation of resorcin, a plan which he has employed, as follows :

A number of shallow parallel incisions about one-quarter of an inch long are made in and around the lesion and through the integument, pain being prevented by the use of a twenty per cent. solution of cocaine and ten per cent. resorcin. Lanolin salve is then applied in a very thick layer to the scarifications. The entire part is enveloped in a strip of lint, which, in turn, is to be thoroughly saturated with the salve, and over this a layer of gutta-percha tissue, absorbent cotton, and moist gauze bandage may be applied in the order mentioned.

Dr. Weiss reports a number of cases in which the employment of this mode of treatment in twenty-four hours produced complete cessation of pain and arrest of inflammation.

Of course it can hardly be expected that this mode of treatment would operate in the more serious cases of periosteal or tendinous inflammation, but it seems well worthy of trial in the less grave forms of phlegmonous inflammation.

THE ACTION OF ARSENIATE OF STRYCHNINE.

FOWLER'S solution, the most ordinarily used of all preparations of arsenic, possesses, together with undoubted advantages, a certain number of objectionable features, which have long been recognized by the practitioner.

The chief advantages of the drug consist in the ease of its resorbability and its signal tonic properties. The principal drawback connected with this useful remedy is the quickly-established habit of the drug on the part of the organism. On account of this habit the physician is naturally forced, if he wishes to continue the use of the drug, to constantly enlarge its dose until the borderline of toxic dosage has been reached. In fact, there are a number of instances recorded where this line was transgressed, and more or less severe intoxications ensued.

Employed subcutaneously, Fowler's solu-

tion is exempt from the disadvantages just stated; but, on the other hand, possesses a very inferior degree of medicinal efficiency. It is, then, with natural interest that we turn our attention to a new combination of arsenic—the arseniate of strychnine—discovered and clinically tested by Dr. J. Russel. Recent issues of *La Semaine Méd.*, *Allgemeine Med. C. Zeitung*, and *Wiener Med. Blätter* (September 9, 1886) devoted considerable space to this novel therapeutic agent.

It is claimed that the drug has given excellent remedial results, and that it acts not only as arsenic but also as strychnine. The preparation, which is soluble in water and glycerin in every proportion, is well suitable for hypodermic medication, produces no pain, and is easily absorbable.

Nevertheless, Russel recommends to use in the beginning only small doses, as a dose containing $\frac{1}{6}$ of a grain of arseniate of strychnine produces toxic symptoms when exhibited in the beginning of the treatment. The author himself employs usually a solution of 1 to 250. He begins with $\frac{1}{4}$ to $\frac{1}{2}$ of a syringe, and gradually arrives at the full syringe, containing $\frac{1}{16}$ of a grain.

Russel states that the effect of the foregoing full dose is peculiarly striking in the premonitory symptoms of the acute infectious diseases, such as malaise, depression, muscular lassitude, etc., the patient feeling revived, as it were, after a single injection. This singular effect of the drug has been so constantly observed by the author in the above conditions that he employs it systematically in all affections marked by a great reduction of vital energy.

The main importance, however, of the new remedy consists in another and entirely different feature,—i.e., in its powerful antiseptic properties, which raise the drug to an agent of the highest rank and service in typhoid fever. Such, at least, is the conviction and the claim of Dr. Russel, who, within the last four years, has repeatedly succeeded by means of this drug to either abort an incipient typhoid fever, or to simplify the morbid process when already fully developed.

The following case, reported by Dr. Russel in this connection, invites our interest. Two sisters were attacked simultaneously by typhoid fever (ileotyphus), and for various reasons one of them alone was given into his care. The doctor injected a Pravaz syringe of the arseniate of strychnine, and had the success in finding his patient after eight days reconvalescing from a light case of abortive

typhoid fever. The other sister was presented for treatment at the tenth day of sickness, when the patient had already entered the second period of the affection. Having instituted here likewise the treatment with arseniate of strychnine, the course of the affection was rendered simple, and recovery soon ensued.

It seems, then, as if the new drug is endowed with great disinfecting powers, capable of sterilizing, as it were, the soil on which the pathogenetic micro-organisms of typhoid fever vegetate.

In addition to this special indication, Russel recommends the drug also in combination with salicylate of iron in chronic anæmia and dyspepsia, and states that he has repeatedly tested the efficacy of the drug in these affections.

TREATMENT OF CHOREA.

IN a recent number of the *Medical and Surgical Reporter*, Dr. Hiram Corson emphatically calls attention to the value of *cimicifuga racemosa* in chorea of childhood. He affirms, as the result of fifty years of experience, that it is always successful in a brief time if a teaspoonful of a good fluid extract be given four times a day. This use of *cimicifuga racemosa* is a very old one, which was insisted upon by the late Dr. George B. Wood, and which, as pupils of that great master, we have long employed.

Some hundreds of cases of chorea have come under our care in the public service at the Philadelphia Hospital, and especially at the University Hospital. In the earlier years the fluid extract of *cimicifuga racemosa* was always relied upon and administered as soon as the patients presented themselves. Experience has emphatically taught us, however, that it is distinctly inferior to arsenic; so that at present every patient coming to the Dispensary with the St. Vitus' dance is put upon the arsenical treatment. In the few cases in which this fails, the next routine administration is of the fluid extract of *cimicifuga*. We can only explain the superiority which *cimicifuga* has asserted over arsenic in the hands of Dr. Corson by the supposition that the doctor has never used arsenic with sufficient freedom.

The arsenical preparation must be given in ascending doses until it produces evidences of its physiological action, and to order this requires a little boldness on the part of the physician. If, however, the patient be well

up, and it thus may act as a background on which new bone may develop.

The fourth form of whitlow described is an inflammation in the sheath of the tendons over the first or second phalanx. It may arise from inflammation spreading from without, or by a purulent inflammation of the synovial sheath of the flexor tendon. The great dangers arising from this form of whitlow are that the tendons may be destroyed, the inflammation extend into the joints, or the pus find its way into the palm of the hand. The finger in this affection soon becomes swollen and flexed, and is the seat of severe throbbing pain, the part is hot, and in the latter stages deep-seated fluctuation may be recognized. If this is allowed to progress, the whole finger may become involved, so as to present two swellings separated by a constriction corresponding to the joint.

The treatment of this affection is identical, according to Mr. Allingham, with that of periosteal whitlow, from which, in fact, the tendinous inflammation can only be recognized with very great difficulty. Mr. Allingham is strongly in favor of treating these affections by lateral incisions, for on account of the difficulty of recognition of the locality of inflammation, should the inflammation be confined to the periosteum, the central incision must be carried through the tendons to reach the bone, of course unnecessarily damaging the tendon. Mr. Allingham, therefore, recommends the lateral incision, claiming for it the following advantages :

First.—As it is difficult to tell whether the whitlow is periosteal or tendinous, by the lateral incision, if it should be periosteal, no damage is done to the tendons by cutting through them.

Second.—By lateral incision the tendons cannot prolapse from their sheaths, and therefore the liability to gangrene is diminished.

Third.—After this method of treatment the finger can be flexed, and so relax all the structures and relieve pain, whereas by the central incision the finger should be kept straight, to prevent the tendons slipping out of their sheaths ; at the same time straightening such inflamed part greatly increases the pain.

Fourth.—If the incisions are on the side they are less likely to be pressed upon, for the cicatrix may become tender, which, if in the centre of the hand, is exposed to pressure every time the hand is closed. Again, a cicatrix in the middle line may contract, and cause the finger to become permanently

flexed, whereas, if the incisions are at the side, such a result could not take place.

So much for the most recent opinions as to the surgical treatment of whitlow, a mode of procedure which is unavoidable when pus has collected.

The less severe forms of furuncular inflammation may be aborted in many cases, according to Dr. Weiss (*Medical Record*, November 27, 1886), by the inoculation of resorcin, a plan which he has employed, as follows :

Having instituted here likewise the treatment with arseniate of strychnine, the course of the affection was rendered simple, and recovery soon ensued.

It seems, then, as if the new drug is endowed with great disinfecting powers, capable of sterilizing, as it were, the soil on which the pathogenetic micro-organisms of typhoid fever vegetate.

In addition to this special indication, Russel recommends the drug also in combination with salicylate of iron in chronic anæmia and dyspepsia, and states that he has repeatedly tested the efficacy of the drug in these affections.

TREATMENT OF CHOREA.

IN a recent number of the *Medical and Surgical Reporter*, Dr. Hiram Corson emphatically calls attention to the value of *cimicifuga racemosa* in chorea of childhood. He affirms, as the result of fifty years of experience, that it is always successful in a brief time if a teaspoonful of a good fluid extract be given four times a day. This use of *cimicifuga racemosa* is a very old one, which was insisted upon by the late Dr. George B. Wood, and which, as pupils of that great master, we have long employed.

Some hundreds of cases of chorea have come under our care in the public service at the Philadelphia Hospital, and especially at the University Hospital. In the earlier years the fluid extract of *cimicifuga racemosa* was always relied upon and administered as soon as the patients presented themselves. Experience has emphatically taught us, however, that it is distinctly inferior to arsenic; so that at present every patient coming to the Dispensary with the St. Vitus' dance is put upon the arsenical treatment. In the few cases in which this fails, the next routine administration is of the fluid extract of *cimicifuga*. We can only explain the superiority which *cimicifuga* has asserted over arsenic in the hands of Dr. Corson by the supposition that the doctor has never used arsenic with sufficient freedom.

The arsenical preparation must be given in ascending doses until it produces evidences of its physiological action, and to order this requires a little boldness on the part of the physician. If, however, the patient be well

watched and the remedy be withdrawn as soon as puffiness appears in the face, no harm can be done. Cimicifuga is not an inert substance, as seems to be thought by some practitioners. Probably much of the cimicifuga that is administered has lost its activity, which appears to depend upon a volatile principle. But we have seen a teaspoonful of the good fluid extract, even in an adult, produce headache, with excessive giddiness and great prostration.

We may add that when, some years ago, the bromide of iron was highly recommended by Dr. Da Costa in the treatment of chorea, we made an extensive and thorough trial of it, and found its therapeutical action as near negative as we can well imagine. In a number of cases it simply did no good at all.

SUBSTITUTION OF DRUGS.

OUR attention has been called by a correspondent to the practice sometimes indulged in by apothecaries of substituting one substance for another in physicians' prescriptions. We do not believe that this is often done; at least we have, in many years of experience with the apothecaries in Philadelphia, never known of such an act. Of course it is unpardonable; and if we had our way, we would send to jail—solitary confinement with hard labor for a term of years—any apothecary who should do such a thing.

Knowing the weakness of human nature, we have always felt great sympathy with a druggist who suffers from having made a mistake in compounding a prescription. The most careful person is liable occasionally to slip; but substitution of one remedy for another, or one preparation for another, is a crime cold-blooded and without excuse. We are not sure that we would have any more compunction in wringing the neck of a person habitually guilty of it than the Western cowboy has in shooting an Indian or mobbing a Chinaman.

MENTHOLEATE, OR SOLUTION OF MENTHOL IN OLEIC ACID.

THERE have appeared from time to time in the THERAPEUTIC GAZETTE articles recommending solutions of menthol, and our attention has been called by correspondents to the fact that these alleged solutions are usually impossibilities. We referred the matter to Professor Joseph P. Remington, of the

Philadelphia College of Pharmacy, who has favored us with the following communication:

"The unsatisfactory character of the solutions of menthol in ordinary use led the writer to try some new solvents with the view of improvement. Alcohol, chloroform, ether, oil of peppermint, and all similar solvents have the disadvantages of too rapid evaporation, and of distributing the menthol over surfaces with which contact is not desired.

"Oleic acid was substituted, and no difficulty was experienced in making a solution as strong as seventy per cent. Now, if menthol is of any value as an external application, its usefulness is probably measured by the extent to which it is absorbed by the skin, and as oleic acid has been proved to be very readily absorbed, the *raison-d'être* of the new solution is disclosed.

"It is best prepared by placing two hundred grains of menthol in a test-tube or beaker, adding half a fluidounce of oleic acid, and heating gently until solution is effected."

THE PREVENTION OF FEVER IN A MALARIOUS COUNTRY.

IN the *Journal d'Hygiène* Schmit notices the popular belief of the inhabitants of malarious countries that cold is a powerful factor in predisposing to malarial intoxication. During the dangerous season such inhabitants always cover themselves carefully.

Popular belief lays great stress on preventive means. Science has not demonstrated a successful vaccination against malaria.

It is true that in such regions races develop which are not affected easily by malaria, but this does not save workmen, travellers, and immigrants from suffering.

Quinine the author considers too short-lived in effect to be more than a palliative means. Tommasi-Crudeli has given the subject much study, and prefers arsenic in doses of $\frac{1}{8}$ grain of arsenious acid in gelatin covering. He has employed this extensively in the worst portions of Italy and Sicily, and among railroad laborers about Rome, with the best results. The remedy is cheap, and easily taken.

In 1883, for example, in the district of Bovino, one of the localities most severely visited by fever, seventy-eight persons were divided into two groups. To one the remedy proposed was given, with the result of perfect immunity, while the remainder were affected by malaria in all grades of severity.

In 657 railroad laborers treated in 1885, 402 were completely exempted, with 119 the results were doubtful, with 136 the treatment was unsuccessful.

A popular remedy, used by the Greeks, Romans, Arabs, and at Gaudeloupe, is the liquid resulting from boiling a finely-cut lemon until the bulk of liquid has been reduced one-third; the juice is filtered, and taken cold.

THE AMERICAN BOOK.

TO the multitudinous answers which the Old World has given to the famous question of Sir Sydney Smith, "Who reads an American book?" must be added the reply of Professor Polotebnov and Dr. Breuv, of St. Petersburg, who have just translated under their supervision the work of Dr. Duhring on the skin, a book which had been previously put into French and Italian.

WE notice, as one of the signs of increasing interest in therapeutics, the formation in Boston of a Therapeutical Society, for which we wish all prosperity and success.

Reports on Therapeutic Progress.

THE MANZANILLA-TREE.

The tree known in Venezuela as the manzanilla has the reputation of causing death to those inhaling air close to it. As to whether this reputation is deserved or not has been investigated by MR. L. JACKSON, who publishes his report in the *Medical Press* for October 13, 1886. On visiting a group of manzanillas, situated on a line of railway, he found them bordering a sheltered hill within a hundred yards of the sea. They were about fourteen in number, mostly luxuriant large trees, about the size of an average full-grown British elm, and slightly resembling them in the clustering of foliage. The leaves had a little of the semitransparency of lime- or linden-leaves, the grouping of leaves rather resembling that of the chestnut, the leaves indented like the plane- or the currant-leaf; the trunk and branches well formed, bark rather smooth, but greenish, perhaps from moss.

On the whole, they were handsome and so well grouped and intact that one wished to stop and sketch them, though the stagnant

air of the place was unpleasant, apart from the risks attending its inhalation. Vegetation flourished in the neighborhood, though grass did not grow absolutely under the trees; but the absence of any mangrove thickets about there was noticeable.

The arrangements made with the agent for their removal were these: that the suitable season should be chosen, and the trees burnt down from the windward side during a favorable prevalent wind, bundles of brushwood to be rolled close with long poles and fired, the supply of which was to be large; the men employed were to have all their requirements as well as their superstitions attended to, besides to be covered and protected by leather all over, also to be provided with masks and gloves.

The agent, now dead, adhered to this proposal and carried it out. On one of the author's visits to the coast, the agent informed Mr. Jackson that almost all those trees had been burnt; about eighteen men had been engaged in it, four or five had died, almost all had been ill. Mr. Jackson saw one of them, who had come about a hundred yards for assistance, about ten days after leaving that work.

He was emaciated, and complained of pains in his limbs, which apparently were of a paralytic nature; he had also had very severe fever, and was apparently quite worn out.

After his departure, the agent said that he considered recovery hopeless in that case, as well as in all the cases of men that had been so employed throughout the undertaking, but that some of the men who had been employed only latterly and for a short time might survive the attacks, which did not at all resemble those of the local fever. He also considered that all the paraphernalia for personal protection had been entirely useless, and had imagined so from the beginning, as he had lived in Mexico and had had some previous knowledge.

The deadly influence of the manzanilla is hence no myth. It evidently produces a special paralytic fever, or combination of paralysis and fever.

There are also several other poisonous trees in the province. In one case, an estate manager, after a journey, was seized with severe pains in the head, followed by swelling of the head to a very large size, though apparently there was neither scratch nor bruise. He was treated medically, and soon recovered entirely; but the assigned cause

was simply the brushing of some branches of a tree or shrub (name unknown) against his head while riding on the journey.

The cases already mentioned cannot have been attributable to other causes. The local fevers, of which the whole of the workmen were victims, are of a depressing and virulent type, and intermittent.

The result of getting wetted in a stream or river, without subsequent rubbing dry, is sure fever of the same sort, but is specially fatal. In fact, the rivers appear to be poisonous on outward application. Damp feet from marsh-wading in Mr. Jackson's own case produced malignant eruptions; at another time he had three days' mild fever from accidentally slipping on the bank of a stream and wetting his head and arm in the fall.

OLEUM SANTALI OSTINDICUM AS AN ANTIBLENNORRHAGIC.

The *Allgemeine Medicinische Centralzeitung*, in Nos. 76 and 78, 1886, publishes a therapeutic discussion of oleum santali from the pen of DR. LETZEL, chief of the Munich Polyclinic for Skin-Diseases, which claims our notice. We condense its important features as follows:

Posner, at a meeting of the Berlin Medical Society, appears to have been the first therapist to call attention to the value of oleum santali in gonorrhœa. Letzel has exhibited the drug since 1885 to nearly one hundred patients affected with gonorrhœa, and is anxious to communicate his results to the profession. At first the oil was given in emulsion, according to the following formula:

- R Olei santali ostind., fʒiiss;
Muc. gumm. arab., q.s. ad emuls.;
Syr. cinnamomi, fʒv;
Extr. fl. coffeæ tostæ (1 to 5), fʒv;
Aque cinnamomi, fʒiv. M.

S.—Take a tablespoonful three times daily after meals.

In nearly one-half of the patients thus treated an unconquerable repugnance against this medication set in in a few days, and forced the doctor to resort to gelatin-capsules, which were readily taken and well borne. The dose of the oil, when given in capsules, was 5 drops twice or three times daily.

Of the one hundred cases treated, four showed a violent gastric or intestinal irritation, manifesting itself by copious diarrhœas or serious dyspeptic troubles. If these graver symptoms were an exception, says the author, lighter manifestations of gastric interference

were almost the rule. Annoying ructus, pressure, and burning in the stomach, and finally a great thirst were almost invariably complained of, though they did not necessitate the discontinuation of the drug. The author lays great stress upon the time of taking the drug, and regards the time intervening between the meals as the most favorable one.

Letzel calls attention to a peculiar symptom which he noted in five of the cases treated by him, viz., a more or less severe congestive pain in the region of the kidneys. In two cases this pain became so intense that morphine had to be given subcutaneously. Posner, in the discussion at the Berlin Medical Society, above referred to, strangely makes no mention of this certainly noteworthy phenomenon, while Jullien, in his "Traité Pratique des Maladies Vénériennes" (second edition, Paris, 1886, fol. 68), refers to this secondary action of the oil. Jullien also describes a peculiar erythema urticatum balsamicum which in one instance resulted from the drug. The eruption appeared on the hands, arms, back, and chest, and soon extended over the entire body surface, attacking also the mucous membranes of the tongue, conjunctiva, and pharynx. The eruption disappeared in the course of another day after a very exhausting sweating.

These observations suffice that oleum santali cannot be regarded as an innocuous remedy. Especially the appearance of congestive symptoms in the kidneys ought to cause the practitioners to use the drug with caution. Patients that are put under this treatment must be informed that when pains in the back occur the remedy must be discontinued.

J. L. Milton ("Pathology and Treatment of Gonorrhœa," fifth edition, London, 1883, p. 109) believes that the truly astounding diversity of professional opinion as to the therapeutic worth of the oil of sandal-wood in gonorrhœa is most probably ascribable to the great differences existing between the single specimens of the drug, the high price of which induces adulterations with castor-oil and balsam of copaiba.

Dr. X. Hager, in his supplement to the "Text-Book on Pharmaceutical Practice," Berlin, 1883, pp. 792-795, gives a series of tests regarding pure oil of sandal-wood.

The following comprises a summary of Letzel's experience with oil of sandal-wood in gonorrhœa:

1. At first the drug decreases considerably the gonorrhœal secretion, and changes its color from green to a milky hue. The pain conse-

quent to urination and erection diminishes, and disappears wholly in a couple of days. (Of forty-two patients treated with the oil thirty-seven were influenced in this manner, while in the seven others no influence upon the gonorrhœal process could be made out.)

2. If after ten to twelve days the medication with the oil is discontinued, the morbid symptoms reappear in an intensified manner.

3. The best results with the oil were obtained if it was not given before the third or fourth week, and if combined with weak astringent solutions (acetate or sulphocarbonate of zinc, resorcin). Three of such cases out of twenty-nine were cured in fourteen days without any injection; in twenty-one cases out of twenty-nine the secretion disappeared in eight to twelve days, the rest of the cure being accomplished with injections. The other eight cases were in indolent, degraded persons, who took not the slightest dietetic or hygienic precautions.

4. In cystitis and gonorrhœal prostatitis the oil has always proven of great value. In nine cases the drug decreased the duration of the affection and lessened the severity of the symptoms.

5. In chronic gonorrhœa the drug produced in many cases a distinct improvement, though its value in this affection is far inferior to the services it renders in acute gonorrhœa.

6. The oil is medicinally more active than oil of copaiba, though a great drawback, alongside of its high price, are the gastric and nephritic disturbances it is apt to create.

THE UNRECORDED INJURY FROM THE CONTINUED USE OF LARGE DOSES OF IRON.

There can be no doubt about the usefulness of large doses of iron in many different stages of disorders, and cases are on record in which 1 to 3 drachms, or even sometimes as much as 1½ to 2 ounces, of the tincture of iron have been given daily in erysipelas; so also ½ ounce of tincture of iron has been given daily to young children, followed by satisfactory results.

In anæmia, which is often dependent upon dyspepsia, the best and quickest way of curing both dyspepsia and anæmia is the administration of large doses of the chloride and sulphate of iron. Large doses of iron act as an immediate stimulant, rapidly removing anæmia, and removing gastro-intestinal catarrh, and renew the appetite and digestion; but if

continued for more than a week or two they cause a gastro-intestinal catarrh of their own, and if this be not attended with diarrhœa, or if a purgative be not given, serious symptoms may ensue.

DR. J. STRAHAN has had such an experience, and calls attention, in the *British Medical Journal* of September 18, 1886, to the danger of obstruction of the bowels which is apt to follow large doses of iron given for any length of time consecutively. The preparations which he has found to cause symptoms of obstruction are as follows, namely:

Ringer's pill of 5 grains of dried sulphate of iron, which equals 9 grains of the ordinary sulphate, ½-drachm and one-drachm doses of the tincture of *mistura ferri composita* P. B., made so strong as to contain 8 or 10 grains of sulphate of iron and carbonate of potassium in each dose. Any of these, if given three times, or even twice, daily, for from one to two weeks, and if natural or artificial diarrhœa do not in the mean time wash out the quantities of insoluble sulphide, will cause severe colic and constipation, which morphine and turpentine stupes seem unable even to alleviate, and which, it seems, would continue indefinitely, or till death, if not removed by a smart saline purge, or other means. Dr. Strahan has seen twenty-four hours of rhythmic agonizing pain, very like labor, with nearly constant vomiting, no sleep or ease after a grain of morphine by the mouth, the temperature rising to 101° Fahr., and great depression of all the powers of life, from a couple of weeks' course of Ringer's pill, which had done immense good to the system at large. This has not occurred once only, but dozens of times. As soon as ever a large dose of any saline—Dr. Strahan prefers an ounce of sulphate of magnesia—has well acted, all symptoms rapidly disappear. At this time, and for twenty-four hours after, the stools seemed composed half of dirty water and half of black sand. The author thinks this latter fact explains the pathology of the matter. In fact, it is a real obstruction—an acute one, too—by quantities of insoluble sulphide of iron. The quantity of this black sand, which comes away when severe constipation and colic have occurred, is surprising. It seems to be much more in quantity than the whole iron ingested, although the stools have been jet-black all along, through excreting the sulphide. So, it seems, it must lodge somewhere; perhaps in the cæcum and appendix. Then, when the iron begins to sicken the patient (gastric

catarrh), the sulphide concretes by mucus, and forms an obstruction which brings matters to a crisis. The length of time that a patient can take large doses of iron depends on the state of the bowels; if they be kept, or remain, slightly loose, he does not suffer at all; if he becomes constipated, the iron soon sickens, and the horrible pains begin; if he were to take a smart saline purge once a week, he could go on indefinitely. The saline gives the quickest relief, because it produces such a vast exosmosis of water from the intestinal wall at all points as to dissolve the mucus which binds the sand, and then washes it out. In extreme constipation, it dissolves fæcal lumps in the same way, except when the masses are enormous. It is thus the best purgative where there is a stricture in the bowels, with dilatation above, as it melts the fæces into a fluid, when they can run through the narrow part.

It is also well known to be the only safe purgative if any inflammatory lesion exist, enteritis or peritonitis. Mr. Lawson Tait takes advantage of this property of salines in his modern treatment of peritonitis ensuing on abdominal section. The principle here seems to be that of giving true and perfect physiological rest by dissolving and washing out all irritants.

Another great advantage the salines have is that they cause no pain, no griping. A teaspoonful of Epsom salts every two or three hours will put an end to many a case of fæcal obstruction in old people, and that without pain, where croton oil and drachm-doses of jalap have only given rise to unendurable pain and collapse.

It cannot, of course, be said that large doses of iron will affect every one in the way described, but in the nature of things it seems to be highly probable. There is excellent reason for the practice of giving large doses of iron. Laache, in "The Relation of Recent Researches on Blood-Corpuscles to Anæmia and Leukæmia" (*Deutsche Med. Woch.*, October 23, 1884), shows that in anæmia it may be both corpuscles and hæmoglobulin in proportionate quantity which are deficient, or, as in true chlorosis, while the red cells are diminished, the hæmoglobin is reduced out of all proportion to the loss of red cells. In fact, in the latter condition, what red cells remain are individually "chlorotic," are not red, or, at least, not red enough. Again, after bleeding, the red cells increase much more rapidly than the hæmoglobin, until, assuming it to be evenly distributed among the corpuscles, it

has sunk to seventy per cent. of the healthy standard. Now, in such cases, the value of large doses of iron is seen. According to Laache, small doses of iron chiefly stimulate the numerical increase of red cells; large doses restore both the number of cells and the amount of hæmoglobin in each. This explains the difference which most men have noticed in practice between the large and the small dose.

URETHAN.

Urethan is the subject of an interesting paper contained in *La France Médicale* (September 14, 1886).

The experiences of UGHI and VAKULOWSKY confirm the conclusions already arrived at by Jaksch, Schmiedeberg, Huchard, Riegel, and other observers, and also correspond with the researches of Eloy in the laboratory of the Bichat Hospital as to the physiological action of the drug.

Urethan, according to these observers, preserves the respiratory functions in its full activity, but lessens the rectal and axillary temperature. Frequently it produces mental excitement. In doses from 6 to 10 drachms (90 to 150 grains) the drug occasionally produces gastric irritation.

In that it does not depress the heart it has an advantage over chloral, but as a pure hypnotic it is not so reliable (*Ann. di Chim. e di Farmacol.*, April, 1886). Vakulowsky prescribed urethan in delirium tremens, rheumatic pains, sleeplessness (cause not stated), and in gastralgia due to carcinoma. In none of these cases did he find it comparable with chloral. On the contrary, he found it to produce gastric troubles in three patients, headache, rigidity of the muscles, and finally a marked weakening of the heart impulse and frequency. These cases, says the editor (*Russkain Meditsina*, No. 14, p. 252), do not invalidate the claims of urethan, but they show the extreme variability of hypnotics.

THE USE OF BORACIC ACID WITH VAGINAL TAMPONS.

In the treatment of the various pelvic troubles where the use of tampons is indicated, one of the disadvantages has been the development of an extremely offensive odor, unpleasant to the physician and distressing to the patient, ordinarily occurring after a retention of the cotton for more than forty-eight hours. Occasions arise when it is inconvenient for the patient to return every two or

three days, and it then becomes a matter of importance to adopt some means which will prevent the usual decomposition and allow her to retain the tampon for a longer period.

To secure this end a number of expedients have been tried, of which DR. HARRIS A. SLOCUM (*Medical News*, October 23, 1886) especially recommends the use of boracic acid. From the first trial it has served the desired purpose effectually, and has given decided and striking results. Cases having profuse and offensive leucorrhœa among the Russians, Poles, and negroes of the Philadelphia Dispensary service have been subjected to this treatment, with the unvarying result of entirely preventing the occurrence of the usual unpleasant odor. In several instances the menses have appeared while the tampons were *in situ*, and have in each case saturated the cotton, which upon removal was found as free from smell as when introduced.

Following is a short description of the mode of application: While using Sims's speculum in either the genupectoral or lateral position, the vagina is cleansed with a piece of wet absorbent cotton held in a pair of uterus forceps, partly withdrawing the speculum to allow of access to the posterior wall. The membrane is then partly dried with a fresh piece of cotton, and several scruples of boracic acid introduced on a spatula, and distributed over the area with a wisp of cotton, or by the aid of the forefinger. The slight moisture permits the powder to adhere, forming a moderately thick coating over the entire wall. In an ointment-jar or other convenient receptacle is placed about an ounce of the acid, and each piece of cotton held in the forceps is thoroughly rubbed in it before insertion.

Great care is always necessary in the introduction of tampons, even when they remain but twenty-four hours, to prevent undue pressure upon the rectum or urethra. When they are to remain in position a week or longer, greater attention than ever must be paid to these points, on account of the tendency of the cotton to pack, through absorption of moisture and continuous pressure.

Comparing boracic acid with other agents, Dr. Slocum has not found one which so completely fulfils its office without offering objectionable features of its own. With very free or unpleasant discharges a proportionately larger amount of powder must be used.

Whether it affects the vaginal tissues advantageously or otherwise the writer is not prepared at present to say, though he has frequently noticed after its use, and when

that which remained from the old packing had been removed with a piece of wet cotton, that the vagina was much paler than when the tampon was introduced. If by repeated trials this observation can be proved correct and constant, it may reasonably form the basis for a series of experiments in the treatment of vaginitis. That the paleness just mentioned is not entirely due to the mere pressure of the cotton seems evident from the fact that simple cotton tampons are frequently tinged with blood on their surface, although carefully placed and not tightly packed.

Oakum tampons seem particularly apt to irritate the membrane, and cause oozing after forty-eight hours' retention. So decided is this tendency to cause bleeding, that when a case presented where it was desired to use oakum, it was not introduced until a layer of cotton had been placed against the vaginal wall to protect it from the harsh and irritating fibres.

Cotton saturated with boroglyceride is an effectual antiseptic, but will not serve the purpose here. Glycerin produces a copious watery discharge, which, though at times beneficial, is not always desirable, and is ill adapted for long retention, inasmuch as it is diluted and partly removed by the watery discharge it causes.

NEW INVESTIGATIONS ON CHOLERA.

TIZZONI and CANTANI send to the *Centralblatt für Medizinischen Wissenschaften* (October, 1886) the valuable results of their observations and researches made during the recent epidemic of cholera at Bologna. The following theses represent their principal conclusions:

1. The nature of the disease was established by bacterioscopic and microscopic examinations.

2. The comma-bacilli obtained in a pure culture from the excrements and the intestinal contents of cholera patients presented all biological and morphological characteristics described by Koch and Van Ermenghem.

3. In twenty-four cases of cholera which were investigated the comma-bacilli could be demonstrated in each instance, either by microscopic researches or (in case the microbes were but few in number) by bacteriological procedures.

4. The bacillus was seen not only in the more or less acute form of cholera (twenty cases), but also in the prodromal diarrhœa (one case) and in choleric typhoid fever (three

cases). In the latter affection the bacillus was obtained as late as six, seven, and fifteen days after the beginning of the infection.

5. These observations testify to the signal value of bacteriological and microscopic researches for the diagnosis and prognosis of Asiatic cholera.

PEROXIDE OF HYDROGEN IN DISEASES OF THE EYE.

Much has recently been written in regard to the use of the peroxide of hydrogen in cases of purulent inflammation of the middle ear. Led by these statements, Dr. J. H. CLAIBORNE (*New York Med. Journal*, September 11, 1886) instituted a number of experiments in cases of catarrhal inflammation of the conjunctiva.

On the instillation of two drops of a ten per cent. solution into the conjunctival sac in chronic catarrh, the following was observed :

The patient invariably started as the drops fell into the eye ; that portion of the conjunctiva which was bathed in the drops became blanched and presented a "washed-out" appearance in from half a minute to one minute after instillation ; this condition lasted at least five minutes ; immediately after introduction the bulbar conjunctival vessels became constricted ; this condition yielded to marked distention in a few minutes ; bubbles rose to the surface of the fluid, and some remained clinging to the bottom and sides of the sac ; twenty to twenty-five minutes after the instillation the eyes presented an irritated appearance, the bulbar vessels remaining still distended and the palpebral conjunctiva equally as red if not redder than before.

The patients complained irregularly of stinging immediately after the introduction, which lasted on an average from one minute to a minute and a quarter. Twenty to twenty-five minutes after the first instillation they invariably stated that their eyes felt better and more comfortable.

In acute cases the same was observed, save that the bulbar vessels became immediately distended after the instillation without apparently becoming smaller in half an hour. No exact difference can be drawn between the effect of a ten and a five per cent. solution, nor between these and a one per cent. solution, save that with the latter the stinging is less and usually lasts only half a minute.

Instillations were made also directly upon the cornea ; there was no change in its appearance ; the stinging was no greater, and

no local anæsthesia occurred under half an hour's observation ; there was no effect upon the pupil. The instillations were made every third day at the clinic. .

The patients were instructed to use no other form of treatment ; they invariably returned with the eyes in a less inflamed condition.

Encouraged by the ultimate result, Dr. Claiborne was bold enough to prescribe a five per cent. solution for one patient with acute follicular conjunctivitis, and to direct him to put two drops into each eye morning and night. He returned on the third day with the eyes much worse. He complained of severe stinging on the introduction of the drops, which, however, soon passed away.

The bulbar vessels were intensely congested and did not yield entirely to several drops of a four per cent. solution of cocaine.

In the light of the foregoing observations, the author does not feel justified in advising the using of the peroxide of hydrogen in eye-diseases, and, although no alarming reaction followed its use in any case, he gladly relegates to others its employment in the eye.

URETHAN AN ANTIDOTE TO STRYCHNINE, RESORCIN, AND PICROTOXINE.

PROF. ANREP has experimentally proven that urethan possesses properties antagonistic to convulsion-producing agents, such as strychnine, resorcin, and picrotoxine, and consequently claims that urethan could be utilized in intoxications caused by the named drugs. The efficacy of urethan rivals in this respect that of hydrate of chloral, but is far less dangerous, as it can, even in large doses, be given with perfect safety. Anrep concludes that in man 2 to 3 drachms of urethan would be required in order to counteract the intoxications with any of the foregoing drugs.—*Pharmac. Post*, October 23, 1886.

CODEINE IN DIABETES.

Notwithstanding the number of papers which have been published as to the value of codeine in the treatment of diabetes, this remedy appears to have made but little progress in the estimation of the profession at large. In the *Australasian Med. Gazette* (May, 1886) Dr. ALFRED A. LENDON reports rather scanty notes of two cases of diabetes, one of which seemed to be a case of pure polyuria, in which the administration

of codeine, in doses of $\frac{1}{4}$ grain, produced immediate relief, decreasing the number of times in which micturition took place and the quantity of urine passed. The other was a case of diabetes mellitus, in a woman 85 years of age, in whom, after restriction in diet had failed to give any benefit, codeine in $\frac{1}{2}$ -grain doses was administered thrice daily, and the quantity gradually increased until she took four grains a day. After six weeks of this treatment, according to Dr. Lendon's notes, she was no better, but rather worse. The thirst was insatiable and the dryness of the mucous membrane of the mouth so great that she was unable to stick a stamp on a letter. The codeine was therefore left off for a time, and after a week resumed at her urgent request, as she fancied that she missed its narcotic effects. It was then given in 3-grain doses at night, and soon increased to 5 at night and to 1 grain in the morning, with marked results, the sugar becoming much less than before, only a trace remaining. The mouth and pharynx became moist and the skin moist instead of harsh and dry. The thirst was no longer a source of complaint, and at night she rested well. She died at the commencement of the hot weather from an attack of acute diarrhoea.

While these notes are quite meagre, they seem to show that codeine possesses a certain amount of influence in preventing the formation of sugar in diabetes mellitus and in controlling the quantity of urine secreted in diabetes insipidus. The results obtained at Dr. Lendon's hands, taken together with the claims made for codeine by Drs. Pavy and Shingleton Smith, show that codeine as a remedy in diabetes is well worthy of further study.

THE ANTAGONISM BETWEEN STRYCHNINE AND COCAINE.

DR. BIGNON (of Lima) communicates to the *Bulletin Général de Thérapeutique* (October 30, 1886) the following results of his experiments on dogs, made in order to define the alleged antagonism between strychnine and cocaine:

1. Cocaine is a physiological antagonist to strychnine.
2. A dog having ingested about $\frac{1}{10}$ grain of strychnine per pound of bodily weight can always be saved by hypodermic injections of cocaine.
3. This experiment succeeds even after the first tetanic paroxysm has set in.
4. Only if too large doses of strychnine

have been ingested the dog perishes from the correspondingly large doses of cocaine required.

THE HYPODERMIC USE OF SPIRITS OF TURPENTINE IN MALIGNANT TUMORS AND OTHER STRUCTURAL DEGENERATIONS.

We have already referred in a previous issue to the favorable results obtained through the hypodermic injection of turpentine in malignant tumors, in the hands of several European surgeons. DR. J. MCF. GASTON reports in the *Southern California Practitioner* for September, 1886, his experience with the injection of undiluted spirits of turpentine in a case of nodular induration and ulceration of tissues that had resisted all the ordinary modes of procedure in such affections. The disease had commenced about five years before, with a thickening and induration of a nodular form, involving all the elements which make up the skin, and, to some extent, the subcutaneous cellular tissue of the lower third of the affected leg. When it was first brought to his attention it did not extend entirely around the leg, and there were only a few points in which ulceration had occurred. But ultimately the tissues became involved throughout an area that could not be covered by two large hands embracing this part of the leg, and broke down into irregular cavernous excavations, interspersed with nodular masses, having an ichorous exudation from the ulcerated apertures that studded the entire surface. The boundary above and below the affected tissue presented a serrated outline, with the structure of the skin unchanged beyond this border-line, and the general nutrition of the body remained apparently unimproved. It may be mentioned that the other leg was amputated below the knee a number of years ago on account of an injury, and that the stump presents nothing worthy of comment.

While nothing definite can be inferred in this case, owing to the interruption of the treatment, there are some points of interest connected with the use of the hypodermic injection of the spirits of turpentine which warrant a reprint of the facts.

An ordinary hypodermic syringe being filled with spirits of turpentine, the point was thrust into the affected tissues and the contents forced into the diseased part. Most intense suffering followed this application, and Dr. McGaston proceeded to inject into the sound structure elsewhere a solution of $\frac{1}{4}$

grain of sulph. morph. and $\frac{1}{16}$ grain of atropine, giving also internally alcoholic stimulants freely. The contortions of the features and the spasmodic respiration resembled the disturbances from an attack of angina pectoris, while the acceleration of the pulse, with marked diminution of its force, indicated serious interference with the vital powers of the patient. In the course of an hour the constitutional trouble passed, and there was slight febrile excitement afterwards. The local irritation and inflammation was controlled by poultices of flaxseed-meal for two or three days, and ultimately disintegration of the deep structures ensued, with a filling up by healthy granulations in this vicinity.

After several weeks another application was preceded by an injection of morphine and atropine. The patient still gave indications of much pain, and seemed to require the repetition of the whiskey in liberal doses. Again the influence upon the new zone of tissue, permeated by the spirits of turpentine, underwent such a modification as to encourage a continuation of the injections.

On the third occasion, however, a four per cent. solution of cocaine was first injected into the part selected for operation. Allowing the needle to remain *in situ*, while the body of the syringe was removed and filled with turpentine, this was now injected without complaint for the time being. But after a half-hour had elapsed the patient began to complain of local pains, which continued for some hours, and caused the refusal of the patient to submit to any further treatment.

SUPERALIMENTATION.

DUJARDIN-BEAUMETZ has made certain deductions from his study of obesity which bear directly upon the question of fattening.

He defines a properly fattening diet as comprising nitrogeneous, starchy, and fatty elements, with an abundance of fluid. Such a regimen may be used as a definite mode of treatment in all conditions of general depression, and also in phthisis.

It must be used under the three conditions which the study of animals has shown necessary to fatten,—namely, consideration of the peculiarities of race, “stalling” (a limited exercise), and a special selection of foods. These conditions are, of course, modified in their application to the human subject.

Practically, as many obese persons eat too little, so many emaciated patients eat too

much. There are cases which cannot be successfully treated through some constitutional peculiarity.

The author speaks of *forced feeding*, as with the insane, and feeding by other than the natural channel, as in cases of stomach intolerance of food.—*Journal d'Hygiène*, November 25, 1886.

THE EFFECTS OF AN OVERDOSE OF COCAINE.

DR. W. E. RAMSDEN WOOD records in the *Australasian Medical Gazette* for August, 1886, the account of a patient in whom an overdose of cocaine produced some alarming symptoms of poisoning. The case was that of a man in whom an injection of three drops of a ten per cent. solution of cocaine was administered to reduce the pain of neuralgia from a diseased tooth, since chloroform was counterindicated on account of heart-disease, and ether proved so exciting that its use had to be abandoned. The next day, the pain being very severe, he sent to his chemist for a similar solution, and had three minims injected, but without the desired effect; he returned to the chemist to make it stronger, which he did, making it twenty per cent. On visiting Dr. Wood, he again received four minims of the twenty per cent. solution, and within five minutes he became restless and inclined to vomit, and then began to feel the sensation of pins and needles in the left hand and arm, which rapidly extended to the right side. This was speedily followed by contraction and rigidity of the fingers, arms, and legs. There was also a tendency to opisthotonos. His pulse became extremely rapid and feeble, his face livid, and the muscles of his mouth and cheek strongly contracted. His respirations were short and convulsive; his hands and feet became cold, and a profuse perspiration broke out on his head and face. Half a tumbler of brandy was administered, followed at short intervals by drachm doses of aromatic spirits of ammonia, and a mustard-plaster was applied over the cardiac region and friction was used upon the upper and lower extremities. At the same time he was made to inhale a few drops of chloroform to check the spasmodic contractions. After continuing these frictions for over an hour he improved somewhat, and the rigidity of the muscles lessened, but returned as soon as friction was stopped. At the end of two hours he improved more rapidly, but felt somewhat

drowsy, and it was not until about four or five hours that all the symptoms had subsided.

THE PHARMACEUTICAL USES OF SACCHARIN.

There seems to be good reason for believing that saccharin has no injurious physiological action when taken internally.

Sir Henry Roscoe has stated that large quantities have been given to dogs, and one dog had as much fed to him daily as was equivalent in sweetening power to a pound of sugar, and did him no harm. Up to the present time it has not been known to produce any injurious effect upon the system, and will therefore probably be more employed in pharmacy. MR. C. J. S. THOMSON, of Manchester, publishes in the *Pharmaceutical Journal* for October 23, 1886, the following notes of some rough experiments made with a view of ascertaining how far the new sweetening principle (saccharin) may be of use in this way. He finds that one per cent. solution of saccharin in hot water, although very sweet to the taste, has a flavor distinctly different from that of cane-sugar. Ninety minims of this solution added to one containing four grains of sulphate of quinine quite masked the bitter taste of the alkaloid and rendered it palatable.

Thirty minims of the same solution sweetened half a drachm of tincture of iron, and it required twenty minims to cover the salty taste of ten grains of bromide of potassium.

BICHLORIDE OF MERCURY IN DIPHTHERIA.

During an epidemic among the population near the Gulf of Finland, where diphtheria has long been extremely fatal, the following treatment, in the hands of DR. VERNER, was very successful.

For young children he dissolved $\frac{1}{4}$ grain of bichloride in 5 ounces of water; for older children, $\frac{1}{3}$ grain in 7 ounces of water; for adults, $\frac{3}{4}$ grain in 16 ounces of water.

These quantities are to be taken by the different patients in from twenty to twenty-four hours, in convenient doses and at convenient intervals. Milk diet only is allowed. Antipyrin is the antipyretic used, and inunctions of ichthyol are ordered three or four times daily. Antipyretics are given in enemata, and the digestion is as carefully conserved as possible.

The author's only bad results in seventeen cases were two, in which scarlatina was a complication.—*Le Nouveaux Remèdes*, No. 19, 1886.

THE MOVEMENTS OF THE HEART AND INTESTINES, ILLUSTRATED BY PHOTOGRAPHY.

At a recent meeting of the New York Academy of Medicine (*N. Y. Med. Journ.*, November 13, 1886), DR. WILLIAM GILMAN THOMPSON exhibited photographs of the normal pulsating heart at the various periods of the pulsation in rabbits, kittens, lizards, pigeons, etc. He also exhibited photographs exhibiting modifications in the movements of the heart consequent upon the administration of various stimuli. In this way he was able to give graphical illustrations of the effects of drugs upon the heart. He had at first employed an ordinary camera, but, as only one plate could be used at a time, he had constructed an apparatus by which he could take six views of the object within a second. The shape of the heart varied very considerably in different animals, but in general the longitudinal diameter exceeded the transverse by about one-fourth in full diastole. The modifications in the form of the heart depended chiefly upon the thick-walled left ventricle. In the open chest the movements of the heart were greatly exaggerated by artificial respiration; if artificial respiration was not maintained the movements might be diminished.

The most important of his later observations were as follows: 1. The base of the heart descended very little, if at all, in systole in most animals. A prominent exception to this rule was seen in the frog. 2. There was much discussion among physiologists as to whether the long diameter was shortened to any appreciable extent in passing from full diastole to full systole. The photographs showed much variation in this matter, and we could hardly judge from what took place in animals as to what took place in the human subject. In most animals there was a slight shortening, but in pigeons there was slight elongation. The transverse diameter was shortened usually twice as much as the longitudinal diameter in full systole. The average shortening of this diameter amounted to from one-quarter to one-third. It was uniform from base to apex, unless interfered with by drugs. The antero-posterior diameter was uniformly elongated by about one-eighth. In a given heart this

diameter was elongated about half as much as the transverse diameter was shortened during systole. 3. The apex, when the pericardium was removed, in birds and mammals, was uniformly tilted forward, upward, and to the right, and the rotary movement of the heart from left to right on its long axis occurred in the excised heart as well as in the heart *in situ*; in other words, it occurred when the base of the heart was free, without vessels to offer resistance to it. 4. The right ventricle lay so much higher, and it was so much thinner-walled than the left, that it exerted much less influence on the shape of the heart during its movements, especially at the apex. The author inferred from his experiments that the cardiac impulse against the chest-wall might be due to the stroke of the apex, and perhaps also partly to the stroke of the anterior and hardened ventricular wall just above the apex.

The apex, as well as the whole contour of the heart, was greatly modified by drugs. Drugs which had the primary effect of increasing the systolic force tended to make the apex sharper, whereas drugs of which the action was to lengthen the diastole, tended to make the apex blunt and round. If antagonistic drugs were given, the whole contour of the heart became more rounded than was natural. The surface of the heart in all its normal changes in size between full diastole and full systole was smooth, but stimulants caused it to become more or less irregular. When the heart was deprived of its blood by hemorrhage, the thick left ventricle retained its shape pretty well, but if the heart was held up, the right ventricle would be seen to pouch out below. The apparent greater vitality of the right side of the heart was observed in the feeble efforts to beat after the left ventricle had ceased its movements. The auricles in systole were uniformly contracted to a slight degree. The independence of the auricles and ventricles of each other in contraction was shown by the photographs. The auricular systole overlapped the ventricular systole in point of time. The extent of movement of the heart as a whole bore no definite relation to its size, but depended altogether upon the amount of work being done. The heart, being removed from its attachments and emptied, filled itself by suction when placed in fluid, and assumed a rounded form. It had been a question whether the coronary arteries were filled during systole, or whether they were closed during systole by the cusps of the valves. If the latter was the case, these

arteries must be filled during ventricular diastole by the elastic recoil of the aorta. The very great prominence of the vessels in the photographs showed that the blood-flow was impeded and dammed back in the superficial vessels by the pressure of the strongly-contracted ventricles. If now, as had been shown by experiments, the coronary arteries were divided during systole, the blood would spurt with some force. The conclusion arrived at by Dr. Thompson was that the coronary arteries were filled by the recoil of blood during diastole, and perhaps also to some extent during systole. By dividing the longitudinal and spiral muscular fibres the contraction of the circular fibres was shown to be uniform and symmetrical. The papillary fibres were shown to stand out towards the centre of the heart and to have independent contractile power. Of the various cardiac stimulants which he had employed, heat produced the strongest systole, and was most uniform in its effect. With aconite he paralyzed the right ventricle, while the left retained its power to contract. Glonoin appeared to be the most powerful chemical cardiac stimulant. Chloral caused marked diastole.

Dr. Thompson had also been successful in photographing the movements of the intestines, bladder, and diaphragm. Scratching the large intestine caused it to contract in ridges, which did not extend far from the point of irritation. The effect of the contraction was to shorten and draw up the entire loop. It was a disputed point as to whether the peristaltic wave passed normally in the reverse direction from the anus up. He had photographed peristaltic waves passing simultaneously in opposite directions; also the pendulum movement of the intestine. Pricking the intestine caused a stricture-like form of contraction.

DR. A. H. SMITH asked whether it was not probable that a systolic murmur was sometimes mistaken for a presystolic one, the observer dating the commencement of the systole from the stroke of the heart against the chest-wall.

DR. THOMPSON did not doubt that systole began before the stroke of the heart against the chest-wall, and consequently such an error in diagnosis might occur.

LIQUOR FERRI ALBUMINATI.

DR. GEMPT has used this solution, originally introduced by Biel, of St. Petersburg, as fol-

lows: in doses of $\frac{1}{2}$ to 1 dessertspoonful, three times daily, in milk; to children, from 5 to 30 drops. Constipation is remedied by Carlsbad salts, taken after the morning dose. This preparation mixes well with milk, containing one-half of one per cent. of oxide of iron.

It is recommended especially in gastric ulcer, and given very recently in hemorrhage. The author gives the following formula for a preparation which will not coagulate milk:

Dried egg albumen, \mathfrak{z} i;
Aqueæ dest. (cold), \mathfrak{z} vi.

Add to the following solution, and shake well:

Liq. ferri sesquichlor., \mathfrak{D} viii;
Cinnamon water, \mathfrak{z} iss;
Glycerin, \mathfrak{z} iss.

Filter. The liquor should be clear, reddish-brown, and contain five per cent. of oxide of iron. Specific gravity, 1.06. Mixed with an equal value of saturated solution of sodium chloride, the albuminate of iron is completely separated. The filtrate should give only a weak reaction for iron.—*Zeitschrift des Österreich. Apotheker-Vereins*, November 10, 1886.

UNALTERABLE ALKALOID SOLUTIONS.

Solutions of cocaine, as those of morphine, atropine, and some other alkaloids, when made with simple distilled water, rapidly become spoiled through the growth of a fungus. DR. ABBOTT (*Medical Press*, October 13, 1886) recommends a solution in camphor-water. He has kept solutions of atropine to which camphor (one grain to the ounce) was added for over a year, and has not seen any micro-organisms develop. The salicylate of these alkaloids has been demonstrated by Mr. Tichborne, of Dublin, to be free from the objection referred to by Dr. Abbott. Their solutions are non-irritant and free from fungoid growths.

CANNABIS INDICA AND BELLADONNA IN WHOOPING-COUGH.

The following formula has been a favorite one with VETLESEN:

\mathcal{R} Ext. cannabis indicæ, grs. xv;
Ext. belladonnæ, grs. viiss;
Alcohol absolute,
Glycerin, aa \mathfrak{z} iss.

In the following doses: Children aged from 8 months to 1 year, 4 to 5 drops; 1 year to

2 years, 5 to 8 drops; 2 years to 4 years, 8 to 12 drops; 4 years to 8 years, 10 to 13 drops; 8 years to 12 years, 12 to 15 drops; over 12 years, 15 to 20 drops.

116 cases were treated, of which 83 did well; of these, 30 made most brilliant recoveries. No evil after-effects were observed in any case.—*Pharmaceutische Centralhalle*, November 11, 1886.

CHLORAL HYDRATE AS A VESICANT.

Attention has quite recently been called to the fact that, for blistering purposes, chloral hydrate is fully as efficacious as cantharides, while it is free from the inconveniences attending the employment of this latter agent. The chloral should be reduced to a powder, and a layer of it placed on a piece of common adhesive plaster, taking care to leave a margin between the edge of the layer of chloral and that of the plaster. This is then warmed over a gas-jet until the chloral becomes discolored and melts, when it should be immediately applied on the spot for the operation, the skin covering which is to be anointed beforehand with olive oil or lard. The anæsthetic properties of the chloral prevent any unpleasant sensation, and fifteen minutes is the maximum period of time during which the application may be continued. If the above-mentioned precaution be taken of anointing the skin, its vitality is retained, and the presence of an open wound is avoided, the skin adhering again as soon as the exudation is evacuated. Another advantage consists in the absence of the risk of poisonous effects consequent on absorption, a by no means uncommon sequel to the use of cantharides.—*Medical Press*, October 13, 1886.

TREATMENT BY INTESTINAL INJECTIONS OF GAS.

CORNIL and CLAUDE BERNARD have drawn the attention of the French Academy to the fact that gases given by rectal injection pass into the lungs and are expired. Carbonic acid gas may be used as a vehicle, and impregnated with medicinal agents.

Bergeon, of Lyons, has given sulphurous acid gas for a chronic bronchitis with most happy results. Chanteron has treated asthmatic and phthisical patients by this method with sulpho-carbonated gas with a direct benefit to respiration; the effect followed half an hour after injection.

In the phthisical a rapid gain in weight occurred. Bergeon recommends 8 to 10 pints of carbonic acid, and from 7 to 10 ounces of sulphur, containing material to be injected slowly into the rectum twice in twenty-four hours.—*Wiener Medizinische Blätter*, November 11, 1886.

THE CAUSES OF THE POISONOUS EFFECTS OF CHLORIC SALTS.

STOKVIS (in Amsterdam) has studied the phenomena produced by large doses of chlorates, and his conclusions are of especial interest in the light of the reported accidents, especially in practice among children, which have occurred with these drugs.

The commonly received explanation for the toxic effects has been twofold, especially with potassium chlorate: first, the local action of its liberated acid radical, and, second, when taken in large doses and entering the blood, through oxidation of the hæmoglobin to methæmoglobin. Stokvis and Von Mering gave animals large doses of chlorates other than potassium to eliminate the influence of that metal. Almost the given amounts appeared in the urine, while there was also an appearance of salts of a lower acid radical. Experiments with potassium salts also showed that salts undergo a reduction in the organism. The reduction of the chlorates, however, was not effected by fibrin, blood-serum, sugar, pus, or the excretions of the body, while these constituents were themselves free from decomposition. Especially was this true of blood and urine.

Jäderholms, Marchand, Mering, and Stokvis have shown that the oxidation of the blood from hæmoglobin to methæmoglobin does not occur without the decomposition of the blood, their studies of blood temperature and other phenomena causing them to consider the process essentially a fermentation. These investigators consider it very doubtful if such oxidation can occur in circulating blood. Injections—intravascular and subcutaneous—of chlorates do not result in the finding of methæmoglobin in the blood in the living animal. In blood drawn from the animal, evidences of the presence of these substances were not wanting. After the administration of large doses to dogs hæmoglobinuria and methæmoglobinuria were only observed when an overpowering intoxication followed. With rabbits, however, both these phenomena occurred, but with evidences of hemorrhage and engorgement of the kidney

parenchyma, and the decomposition of such extravasated blood would readily account for methæmoglobin in the urine. We see, then, how all salts, when circulating in a given concentration, can produce derangement in the relative composition of the body fluids, the decomposition of these fluids, local engorgements, injury to the tissues, and finally the changes which the presence of fermentation makes possible. The author considers not potassium chlorate alone, but all salts, and especially all the potassium salts, capable of such action.

AN IMPROVED TROCAR FOR PARACENTESIS OF THE ABDOMEN.

The frequent obstruction of the canula by the intestine or omentum in the operation of tapping, which generally occurs when about a pint of fluid has been withdrawn, renders the improvement in the form of canula suggested by Dr. JOHN S. MILLER (*Annals of Surgery*, November, 1886) of considerable value, especially since the various manœuvres usually resorted to, such as endeavoring to float away the obstruction by changing the patient's position, or the dangerous plan of introducing a probe through the canula, are generally without success.

The device which Dr. Miller employs is to introduce a smaller and longer canula into that already in position, in case there is an obstruction to the flow. The canula is blunt, and provided with two long fenestræ. In the latter are springs which expand and push away the obstruction on emerging from the original canula, and which are so solidly soldered as to offer no danger of breaking off in the abdominal cavity.

In reply to the query whether or not the gut may be incarcerated and wounded by the springs, Dr. Miller states that in several operations no such accident occurred, when all efforts in bringing about such a complication upon the recent cadaver were unsuccessful.

THE EFFECT OF LARGE DOSES OF COCAINE UPON THE CENTRAL NERVOUS SYSTEM.

DR. BEY, of Cairo, has had the following experience in the use of cocaine as a means of checking the opium-habit. He began with doses of 5 centigrammes, three or four times daily, but the patient's sensations of relief and stimulation were so pleasurable that the patient soon established a cocaine-habit. He sought relief for each slight ailment in an

injection of cocaine, the dose increasing until $\frac{1}{2}$ a gramme, and even $\frac{1}{8}$ of a gramme, was taken secretly daily. This produced loss of appetite, great irritability, ringing in the ears, and, from time to time, dyspnoea and hallucinations of sight and hearing. These unpleasant symptoms the patient had learned to relieve by injections of morphine until he became skilled in the antagonistic use of the drugs. An attack of herpes and its neuralgic pains drove him to double his doses of cocaine until for two or three days he took a gramme, and at times $1\frac{1}{2}$ grammes daily. Then followed a condition very like delirium tremens,—tremors, lack of muscular tonicity, incontinence of urine, alterations in the nails of the fingers and toes, the greatest agitation, severe hallucinations of sight, hearing, and smell, injected conjunctivæ, a staring expression. He fired a pistol at imaginary objects, attacked his servant, and was finally placed under hospital restraint. Here he soon recovered under morphine injections of 5 centigrammes, three times daily.

RARE LESIONS PRODUCED BY BROMIDE OF POTASSIUM.

At a recent meeting of the New York Pathological Society (*N. Y. Med. Journ.*, November 13, 1886) Dr. R. W. AMIDON presented an epileptic young woman, who had been under his care four years, taking moderate doses of bromide of potassium,—perhaps never more than 4 or 5 drachms a day. A little over a year ago she discontinued it, but recently he learned that she had been taking during the past eighteen months a mixture of the bromides amounting to 6 drachms a day. She then returned to him, and he found the ordinary acne on the face, which, although usually confined to the face and neck, perhaps occasionally reaching to the chest and shoulders, had in this patient, as in two others whom he had seen, invaded the legs, and assumed almost the pustular form. The lesion began in the ordinary way, but became indurated with rather a large base, and ran a chronic course, breaking down and forming what appeared to be a small ulcer. Vesicles, with contents which tended to become cloudy and purulent, formed in rings about the acne spot. After a time the centre of the spot took on a reparative process, and entirely healed, while the pathological changes at the periphery spread, and the vesicles became purulent, dried up, and formed a brownish scab. A section of one of these spots showed

that there had not been a true ulcer, but that the skin had simply been denuded of the cuticle, leaving the papillæ intact. He had in no case seen the true skin indurated. The disease did not seem to depend particularly upon the amount of the bromides given. The only treatment which he had seen do good was the thorough application of the actual cautery.

NEW HÆMOSTATICS.

BONAFoux recommends the following powder, whose use in the human subject and in experiments on animals has resulted in the prompt checking of bleeding, and the rapid obliteration of the vessel afterwards:

Colophonium,
Gum-arabic,
Charcoal, in equal parts.

Dr. SPARK has used in his operations about the mouth and throat chloroform and water, in proportion of two to one hundred.

As a simple gargle, especially after the removal of tonsils, it has been very satisfactory. As a hæmostatic douche, it acts promptly, and does not impede the work of the operator.—*Pharmaceutische Post*, October 30, 1886.

NOTE ON THE TREATMENT OF THREAD-WORMS IN CHILDREN.

The complete cure of thread-worms in children is often very difficult. While the ordinary methods used, such as rectal injections of salt and water, infusion of quassia, and other remedies, do good for a time, yet they often fail to relieve the attendant symptoms of "worms," symptoms usually very irregular, and in some cases severe, in character. In many cases, though the irritation about the anus is relieved by injections, the irregularity of the bowels and the disturbance of sleep remain the same. This is probably due to the fact that the habitat of the worms is higher up in the large intestine, where no remedy introduced by the rectum can reach them.

In many cases Dr. SIDNEY MARTIN (*Practitioner*, October, 1886) claims to have found that rhubarb in small doses brings away large numbers of worms, and at the same time regulates the bowels, so that the use of injections may in most cases be dispensed with. The formula which he has found most useful is as follows, varying slightly with the age of the child:

R Tincturæ rhei, ℥iij;
Magnesii carbonatis, gr. iij;
Tincturæ Zingiberis, ℥i;
Aquam, ad ℥i.

This is to be taken twice or three times daily, according to the effect on the bowels. Whether the rhubarb acts as a vermicide, or simply by "moving the worms on," the writer is unable to say.

INFLUENCE OF DRUGS GIVEN TO NURSES OR MOTHERS ON THEIR SUCKLING INFANTS.

We abstract from *Les Nouveaux Remèdes* of August 1, 1886, the following interesting discussion of DR. FEHLING relating to the influence of certain drugs given to nurses on their suckling babies.

1. *Salicylate of Sodium*.—Dose varying between 30 and 45 grains. Whenever the child is put to the breast one hour or less after the administration of the drug, the salicylate of sodium can be found in the child's urine. After the expiration of twenty-four hours no traces of it can be found in the urine. Likewise the salt cannot be recovered if the child is put to the breast very soon after the exhibition of the drug. The elimination of the drug terminates simultaneously in nurse and child.

2. *Iodide of Potassium*.—The same results are obtainable. The milk, if analyzed, gives the characteristic reaction. In the child the elimination lasts seventy-two hours; in the nurse forty-four hours.

3. *Ferrocyanide of Potassium*.—The reaction is very distinct in the urine of the nurse, but wholly absent in the child's urine.

4. *Iodoform*.—After prolonged application of iodoform upon wounds of the vagina or vulva, iodine can be recovered from the milk and urine of the nurse, but never from the child's urine.

5. *Mercury*.—The transmission of mercury from the nurse to the mother is very slight and inconstant.

6. The influence of the nurse's diet on the child is illusory; nurses can with impunity eat sour articles (lemons, vinegar) without thereby influencing the child.

7. *Narcotics*.—(a) Tincture of opium in 20- to 25-drop doses. Thornhill claims to have observed a prolongation of the sleep in infants, while Fehling saw neither prolongation of sleep nor constipation resulting from it. (b) Hydrochlorate of morphine. The drug given in medicinal doses does not influence the child. (c) Chloral. Dose 15 to 45 grains.

Average length of sleep produced in nurse, two hours. No effects on the child are observable if it is strong and vigorous. If the child is weak and possibly born before the full term, it is advisable to wait two hours after administration of the drug to the nurse before allowing it to suckle. (a) Sulphate of atropine. Injected in the usual doses hypodermically in the nurse, the drug produces very distinct physiological effects in the child. The dilatation of the pupils taking place in the child does not disappear before twenty-four hours. Hence minute doses of the drug exclusively are permissible.

MILK AS A PROPHYLACTIC AGAINST RENAL ALBUMINURIA IN PATIENTS WITH SCARLATINA.

MUSATTI has combined milk diet and cold baths in scarlatina, with the best results both in mitigating the severity of the fever and in preventing the nephritis which so often occurs. He employs milk from the beginning of the disease, and he has not seen the evil effects of cold bathing in causing renal congestion and irritation, of which others have spoken. With due care against shock and collapse, he would repeat the cold application every two hours if needed. Jaccoud is quoted as supporting the author's use of milk.

HYDRASTIS CANADENSIS NOT AN OXY- TOCIC IN THE HUMAN SUBJECT.

SCHATZ has reviewed the experiments of Fellner upon animals, and has observed the effects of the drug upon human beings, without finding the markedly oxytocic effects seen in animals. The peristalsis of the genital tract seen in animals Schatz considers due to the strongly-contracted blood-vessels, and not to muscular stimulation. The peculiar property of the hydrastis to contract the uterine blood-vessels, but not its muscle, makes its use indicated in the following cases: in uterine hemorrhage from myomata; in an eccentrically hypertrophied uterus, which, when emptied of its contents, relaxes, and bleeding recurs; in hyperæmia of the genitalia, where ergot does not result in contraction, and intermittent pains and relaxation increase the hyperæmia; in acute or chronic pyosalpinx, where it is desirable to contract the tube to lessen hyperæmia; in chronic peritonitis and oöphoritis. Hydrastis does not derange digestion as digitalis does.—*Medicinisch-Chirurgische Rundschau*, November 15, 1886.

METHYLAL.

Attention has been called by SIGNOR PERSONALI (*Nouv. Rem.*, October 15, p. 459), of the Pharmacological Institute of Turin, to the possible value as an anæsthetic and hypnotic of methylal, a compound which was first obtained nearly half a century ago, but has hitherto remained without application. Methylal is represented by Roscoe and Schorlemmer ("Hist. Carb. Comp.," p. 195) as having probably the constitution $\text{CH}_2(\text{OCH}_3)_2$. It is prepared by distilling methyl alcohol with an oxidizing mixture of manganese dioxide and sulphuric acid, and treating the distillate with potash lye to separate methyl formate, which passes over with the methylal. The methylal is a very mobile, volatile, colorless liquid, sp. gr. 0.3551, boiling at 42°C ., and slightly reddening litmus-paper. It has an odor recalling those of chloroform and acetic ether, and a burning aromatic taste, but produces a sensation of cold when placed on the skin. When injected subcutaneously into dogs in the proportion of 0.10 to 0.15 per cent. of their weight it quickly produced anæsthesia, followed by a deep sleep, in which reflex action was suspended. Rabbits were not quite so susceptible. Recovery was rapid in consequence of the rapid elimination of the methylal, which did not appear to leave any disagreeable after-effects. It augmented slightly the heart-beats, lowered slightly the blood-pressure, and caused the respiration to become slower and deeper. Signor Personali has found methylal also to be an antidote to strychnine, a small quantity being sufficient to suspend the tetanic spasms. In the human subject it is said to relieve nervous pains of the stomach when administered as a draught, and in the form of an ointment or liniment to constitute an excellent anæsthetic. Several formulæ are given, among which are a liniment (oil of almonds, 35 grammes; methylal, 15 gr.), an ointment (lard, 30 gr.; wax, 3 gr.; methylal, 5 gr.), a "potion" (syrup of red currants, 40 gr.; methylal, 1 gr.; water, 110 gr.), and a syrup (methylal, 1.5 gr.; simple syrup, 100 gr.).—*The Pharmaceutical Journal and Transactions*, October 30, 1886.

THE PHYSIOLOGICAL ACTION OF ACETOPHENONE.

DR. MAGNIAN denies the hypnotic effects which others have ascribed to this drug.

The author gave an animal a toxic dose, with the following effects: lessening of ar-

terial tension, acceleration of pulse and respiration, which became slow as the stage of intoxication became advanced.

No great alterations were observed in the gases of the blood; the amount of oxygen especially is not lessened, while the amount of urea excreted is greatly lessened.—*Revue de Médecine*, November 10, 1886.

USES OF HYOSCYAMINE.

An interesting discussion took place before the meeting of the New York Neurological Society on October 5, which we reproduce as reported by the *New York Medical Journal* of November 13, 1886:

The president, DR. C. L. DANA, stated that there were two preparations of the drug, the crystalline and the amorphous. The former seemed to be similar in property to the opiates, while the latter seemed to have neurotic properties. He had heard that hyoscyamine was employed in the asylums for the insane in New York, but not very successfully; whereas in the asylums of Pennsylvania its success had been marked. He had employed hyoscyamine in paralysis agitans, in chorea, and in a few cases as a hypnotic, and it had been employed as a hypnotic to a considerable extent in his service at Bellevue Hospital. The number of cases of chorea in which he had used it was six; in three it was noted to have been of benefit, or to have caused very rapid or very marked improvement. One of the cases was marked, and had not yielded to other treatment. In three cases the results were very doubtful. He had employed it in four cases of paralysis agitans,—in two, he thought, with unquestionable benefit. In two it seemed to produce no benefit. On the whole, he thought that, unless given at rather an early stage of paralysis agitans, it did no good. The form employed in chorea and paralysis agitans was the crystalline, but he was not sure that the amorphous form would not be the better preparation in such cases. He thought we could get along perhaps as well without as with hyoscyamine.

DR. B. SACHS's experience with hyoscyamine had not been very extensive, but he had employed it in a few cases of paralysis agitans, acute mania, and the insomnia accompanying the neurasthenic condition. He had employed only the crystalline form. In contradistinction to what the president had said, that it was best to give it in the early stage of

paralysis agitans, he remembered one case in which every other therapeutic agent had been tried without success, when hyoscyamine was administered in about $\frac{1}{100}$ of a grain dosed twice a day, with the effect of making the patient very much more comfortable, and of diminishing somewhat the annoying movements of the hand. In another chronic case it had been of no benefit. He had obtained no effect from the drug in allaying the excitement of acute mania. It had also been disappointing in insomnia accompanying neurasthenia. It seemed to be of more value against insomnia from mental restlessness.

DR. W. M. LESZYNSKY said that about eight years ago it was quite fashionable to use hyoscyamine in asylum practice, and he had employed it in chronic mania, acute mania, and epileptic forms of insanity. First he used the amorphous form, and afterwards the sulphate. It had been said that the latter form was easier absorbed, and produced its effects in smaller doses. The sulphate was also preferred for hypodermic use, in which manner he had employed it in $\frac{1}{80}$ of a grain doses. To patients with recurring attacks of maniacal symptoms the drug was given a few days before an expected attack, and continued until the attack was aborted. In a state of exhaustion he would regard hyoscyamine as a dangerous drug to administer; but where there was no objection to its use on that ground, he had known it to produce sleep where chloral and morphine had failed. Given to patients subject to epileptoid convulsions before menstruation, it had seemed to avert the attack. He had given it in small doses in two or three cases of chorea, and thought it produced some benefit.

DR. GRAY had been using hyoscyamine ever since it had been introduced to the profession, and he must say that for certain purposes there was no drug that he could not better afford to dispense with. The most convenient form was in tablets, $\frac{1}{100}$ of a grain each. In some people hyoscyamine would produce seemingly serious retention of urine. It might also produce disastrous results if given to persons whose general strength was below par. In an old gentleman with atheromatous arteries, hypertrophied and feeble heart, $\frac{1}{100}$ of a grain had caused a condition of collapse. He knew of one patient suffering with melancholia whose death had been hastened by it. He had given it in two cases of chorea, one being an exceedingly violent case. The child finally died in a convulsion. To that patient he could never give a

second dose of hyoscyamine, because of the alarming prostration which a first dose would cause. In another case, in which the child had to be held in bed, the drug proved an effective means of restraint, but the child was always found prostrated to a marked degree the next day. In paralysis agitans it had been very useful, and its use had come to be with him a routine treatment. He thought the reason why it had been of more benefit in his practice was that he combined with it some stimulant or tonic to prevent its depressing effect. He gave with it good food, 1 or 2 grains of quinine a day, and sometimes alcoholic stimulants. He had satisfied himself that it was the hyoscyamine in this treatment which had a restraining effect upon the movements in paralysis agitans. But it was especially in cases of mental trouble that hyoscyamine was of great benefit. In insanity with hallucinatory symptoms, especially in the early stage before the patient could be taken to an asylum, hyoscyamine would do much towards restraining him, and, it would seem, aided in cutting short the disease. He was very careful to give no more of the drug than was absolutely necessary, and he combined it with bromide of potassium, which increased its effect. He had never seen a hypnotic effect from hyoscyamine.

DR. THOMSON'S experience with hyoscyamine, almost from the beginning, had rather prejudiced him against it. One of the first cases in which he had employed it was that of a judge troubled with insomnia. The next day he was unable to hold court, and had bladder symptoms, etc. He had found it useful in asthma with considerable dilatation of the right side of the heart, without bronchitis, but a congested state of the lungs. He had employed it in facial neuralgia, headaches, and various neurasthenic conditions, but had nothing definite to say about its effects. One patient with paralysis agitans was benefited by it among many with whom it was a failure.

DR. KELLOGG had used hyoscyamine in cases of mental excitement. It had not proved the sedative he had supposed it would, but it controlled muscular excitement. He had failed to get any hypnotic effect from it. He had not been favorably impressed with its after-effect in acute mania.

DR. H. S. HINKLEY had found it serviceable in allaying maniacal excitement.

DR. RICHARDS had given from 5 to 7 drops of a one per cent. solution in several cases of insomnia, without effect.

THE INFLUENCE OF FLUIDS UPON THE TEMPERATURE OF FEVER PATIENTS.

GLAX has observed, in long clinical experience, that the consumption of abundant fluids by fever patients is followed by a rise of temperature. A retention of fluids follows their ingestion, and the lessened vascular tone and the slow capillary circulation result in a free oxidation of individual cell-elements. This occasions a rise in temperature, which ends as the fluids find exit through the kidneys.—*Medicinisch-Chirurgische Rundschau*, December 1, 1886.

THE TREATMENT OF VARICOSE VEINS BY INJECTIONS OF CARBOLIC ACID.

SURGEON-MAJOR W. F. STEVENSON states in the *Lancet* (October 23, 1886) that in the last two years and a half he has treated eight cases of varicose vein, some of considerable severity, by the injection of carbolic acid, as recommended by Mr. Cheyne, with the most desirable results, and with no ill effect whatever.

The treatment consists in the injection of one minim of pure carbolic acid at different situations into the enlarged veins, having previously cut off the circulation from the limb by means of an elastic bandage placed above the highest point of puncture. For the latter purpose the tube of an Esmarch's apparatus is best, but a Martin's bandage or two or three yards of elastic webbing will do excellently. Before operating the patient should be directed to stand erect or to sit on the edge of his bed, with his heels on the floor, for about two minutes, in order to allow the veins to become distended. The Esmarch tube should then be passed around the thigh one and a half times, sufficiently tight to stop the superficial venous circulation, and a little time (about a minute) given for the vessels to become well filled below it, the remainder of the tube being then applied so as to cut off all circulation from the limb. Injections of pure carbolic acid, 1 minim each, are then made into the veins at about one inch and a half apart, as many as may be required for each case. A little pledget of absorbent carbolized cotton-wool is placed over each puncture as the needle is withdrawn, and well soaked with collodion. This is allowed to remain until in the course of time it falls off, when healing will usually be found completed. The elastic bandage cutting off the blood-supply should not be removed in less than fifteen minutes after the last injection has

been made, and great care should then be taken not to remove it suddenly. The circulation should only be permitted to return by very slow degrees. For at least a week after the operation the patient should not assume the erect position, or put his foot to the ground for any purpose whatever. The pain is very slight; besides that of the pricks of the needle, a burning sensation is felt at the seat of each puncture, lasting for ten minutes or less, and even this is not severe. Certainly no anæsthetic is required. Care should be taken that the subcutaneous injection syringe and needle are "surgically clean," and to insure this they should have been placed in a 1 in 20 carbolic lotion for about twelve hours previously to use. The author has done as many as eighteen injections in one case, and it seems advisable to begin with the injection next to the elastic bandage; that is, the one highest on the limb. Getting the point of the needle well into the vein is not quite so easy a matter as might at first appear; attempts to do so at right angles to it frequently fail, and the injection is thus made into the surrounding tissue. The best plan is to fix the skin over the vessel by means of the left thumb, close below the point selected for puncture, and to direct the needle through the skin and coats of the vein in the long axis of the latter. Mr. Stevenson thinks that in his cases somewhere about ten per cent. of the punctures caused suppuration, a little abscess about the size of a pea forming where this occurred; but this process, as the result of the caustic action of carbolic acid, was curiously slow and almost absolutely painless. Three of his cases were done to remove the cause of varicose ulcers of the leg, which had been healed over and over again by rest in bed and different means of local treatment, but which had broken out afresh on the patient's commencing to get about again.

PATHOLOGY AND THERAPY OF FEVERS.

PROF. FINKLER considers that by our studies of the nervous system, by the large number of agents which depress temperature, and from our knowledge of infection we are able to form a reasonable hypothesis regarding the phenomena known as fever. It is proven that the heat-producing and regulating mechanism of the body is at fault; and he considers that the three stages of the fever's development are especially instructive, as throwing light on its subsequent course.

The writer believes that Pflüger's labora-

tory researches have shown that fever is a neurosis, a paralysis of the centre which governs temperature. The phenomena of fever are dependent upon temperature; these phenomena form a useful reaction against the effects of a toxic agent. He observes that antifebrile treatment by baths must be given with reference to the laws governing the nervous mechanism of heat, and when so given is of the greatest value.

Drugs which directly influence fever exist, but have few grounds of decided worth.

Combined treatment by baths and specifics he considers the most efficient.—*Medicisch-Chirurgische Rundschau*, December 1, 1886.

A NEW OPERATION FOR HYPOSPADIAS.

MR. T. N. FITZGERALD states in the *Australian Medical Journal* for September 15, 1886, that after having tried most of the feasible and recognized operations for the relief of hypospadias, the results in most cases being disappointing, he conceived the idea that if a subcutaneous opening could be made to simulate in size and shape as nearly as possible the natural urethra, the instrument not to crush but divide the structures, and this opening kept patulous with some smooth, unabsorbent material, success might be possible. Accordingly, he has carried out this plan in two instances, and in both with perfect success, and he reports tolerable full notes of one of these cases.

This was a child aged 8 years, in whom at first the sex was not easily discernible. Both testicles were high up in the canals at the interior rings and the scrotum flattened out. The diminutive penis was drawn down upon the perineum, and the rudimentary corpora cavernosa difficult to be distinguished. The urethral opening was close to the scrotum, making this a case of peno-scrotal hypospadias. Having carefully examined the case, Mr. Fitzgerald decided to free the penis by a careful dissection, and then attempted to form the urethra, raising the glans and making a free transverse incision, as recommended by Duplay. The strong fibrous bands which existed under the corpora cavernosa and curving round them were freely divided. After a little troublesome dissection the body of the diminutive organ was raised up and the lozenge incision brought together laterally by horse-hair sutures. A wire stage was erected on the pubis, the little penis transfixed by a hare-lip pin, and fixed in position with fine silver wire. The case did remarkably well,

and in about six weeks was discharged with instructions to return in six months to undergo the second operation, namely, the forming of a new urethra.

On his second return, after nearly a year, chloroform having again been administered, he was placed in the lithotomy position and the second part of the operation completed. The distance from the end of the penis to the urethral orifice was about two inches. The organ was put on the stretch in the vertical position, and a long, sharp tenotome introduced in a slight indentation where the urethral orifice in the normal state ought to have been, and gently pushed downwards and backwards to a site a little behind and to the side of the hypospadias opening. The channel thus made a vertical slit simulating the normal urethra as much as possible.

A previously-prepared glass rod, about the size of a number six English bougie, well oiled, was then passed down the newly-made canal, and allowed to project just below and to the side of the lower opening. The penis was held upwards, and the glass rod fixed in position by the aid of a wire stage erected on the pelvis. The case after operation did very well. The urine ultimately being passed out of the artificial urethra, which became lined with mucous membrane, and the slight fistula which remained at the site of the hypospadias opening being readily cured by paring the edges and inserting a suture. Mr. Fitzgerald states that the boy is now perfectly well, and able to void all his water in a good stream by the new passage.

THALLIN IN DISEASES OF CHILDREN.

STEFFEN writes in praise of thallin in fevers in children because of its ready solubility in water, its freedom from disagreeable taste, its prompt effect, and lack of ill after-effect. A depression of temperature occurs an hour after taking, and persists three or four hours. The doses range from $\frac{3}{4}$ of a grain to 2 grains, and rarely need be repeated more often than twice in twenty-four hours.

The fall of temperature ranges from a degree and a half to four; this is dependent not only upon the patient's peculiarities, but varies with different hyperpyrexias. In typhoid fever and in lung-diseases the greatest effect is observed; in scarlatina, measles, and diphtheria the result is least apparent. In rare cases only, when the temperature rises rapidly a second time, a decided chill and cyanosis, but without collapse, have followed

the reduction of temperature by thallin.—*Medicinisch-Chirurgische Rundschau*, December 1, 1886.

MEDICATION OF NERVES.

DR. J. LEONARD CORNING recommends for the treatment of nervous affections, in the *New York Medical Monthly* for November, 1886, the method which he described some time ago, of prolonging the anæsthesia produced by hypodermic injections of cocaine through the suspension of the circulation in the part. He reports three cases of sciatica in which he injected 100 minims of a one-half per cent. solution of cocaine at the more painful points along the course of the nerve, and immediately thereafter applied a tourniquet in such wise as to interrupt the circulation in the crural above the point of injection. During the first five or ten minutes after this injection little relief was experienced, and after a lapse of twenty minutes the pain had sensibly diminished and in half an hour had entirely disappeared. After the removal of the tourniquet pain did not return until the following day, and the mode of treatment was repeated for three weeks, the periods of freedom from pain becoming longer and longer until the pain finally totally disappeared; and now, four months after the last injection, there has been no return of the pain.

PHENYLHYDRACIN A SUGAR-TEST IN URINALYSIS.

DR. VON JAKSCH, assistant to Prof. Nothnagel in Vienna, employs this substance as follows: Twice as much of the powdered chemical as will lie on a knife-point and four times the quantity of sodium acetate are added to half a test-tube of water which is slightly warmed; an equal volume of the suspected fluid is added, and the mixture heated for twenty minutes in a water-bath, after which it is placed in cold water. If a large amount of grape-sugar be present a yellow crystalline precipitate will form, which on microscopic examination is seen to be composed of needles of yellowish color, alone or in bundles. With large amounts of sugar this precipitate becomes macroscopic.

If no precipitate but a cloudiness results, the liquid is put in a conical glass and again examined, when a few crystals denote a trace of sugar, amorphous yellow matter meaning nothing.

This test is especially useful in cases of

poisoning from coal-gas, etc.; also after deep chloroform narcosis and the taking of a large amount of salicylic acid, and in transudates and exudates in the abdomen or thorax.

The author's experience would recommend phenylhydracin most highly as a clinical reagent.—*Deutsche Medicinal Zeitung*, November 8, 1886.

SACCHARIN.

The alleged antifermentative property of saccharin has been the subject of a comprehensive series of experiments by MESSRS. ADUCCO and MOSO (*Chem. Zeit.*, October 10, p. 218). It was found that in the proportion of 0.16 per cent. saccharin distinctively and persistently diminished the activity of beer yeast at a temperature both of 16° and 30° C. In a mixture of equal parts of 0.32 per cent. saccharin solution and urine, kept at a temperature of 16° to 17° C., ammoniacal fermentation had not commenced at the end of seven days, while a mixture containing the same proportion of salicylic acid had broken down. A saccharin solution retarded the lactic acid fermentation in milk, and the action of a preparation of pancreas was also considerably slackened by it. Added to a pepsin solution in the proportion of 0.16 to 0.32 per cent. saccharin retarded the peptonizing of coagulated albumen, though without stopping it, but upon reduction of the saccharin to 0.0064 per cent. the gastric juice was then scarcely affected. Comparative experiments showed benzoic acid to be equally powerful in this respect, and salicylic acid a little more so. In the proportion of 0.16 to 0.32 per cent. in acid and neutral solutions saccharin proved capable of affecting the amylolytic action of saliva, the effect being least in the neutral solutions. Salicylic acid proved rather more powerful in similar solutions, and boric acid had about the same effect as saccharin. Professor Salkowsky also reports results that are perfectly in accord with the foregoing (*Chem. Zeit.*, October 10, p. 218). He states that the antiseptic property of saccharin is due to an acid action, and is greatly diminished upon neutralizing with sodium carbonate.—*Pharmaceutical Journal and Transactions*, October 30, 1886.

THE TREATMENT OF CHRONIC DIARRHŒA BY SULPHOCARBONATED WATER.

DR. DE CHAMPEAUX reports in *Bull. Gén. de Thérapeutique*, November 15, 1886, two cases

in patients greatly enfeebled by exposure at sea and in the tropics where foeculent, chronic diarrhoea was cured by this agent.

It was given in doses of from 20 to 60 grammes (f3v to xv) in milk during the twenty-four hours, and as an adjuvant to tonic and astringent drugs.

Its use must be patiently continued, and the results are obtained only after prolonged use.

Its mode of action is explained by Dujardin-Beaumetz as being disinfectant, destroying micro-organisms and neutralizing ptomaines, and thus removing the irritating causes which keep up the intestinal lesion. It may be prepared in the following formula :

Bisulphide of carbon, ʒvi¼ ;
Water, Oi ;
Essence of mint, 30 drops.

Place in a flask containing three pints. Shake thoroughly.

THE TREATMENT OF INTUSSUSCEPTION BY INFLATION AND MASSAGE.

DR. B. W. CHEAVLE reports in the *London Lancet* for October 23, 1886, three successive cases of intussusception, occurring in children, successfully treated in this way. The method which he employed in these three cases was to inject air into the rectum by means of Higginson's syringe, at the same time kneading the abdomen externally. It was found that at least three assistants were required to carry on this operation satisfactorily : one to work the syringe, one to press the anus to prevent the escape of air, and the third to manipulate the abdomen. His experience in these three cases has been that the tumor will disappear after some minutes, and should it return, may be again removed by a repetition of this procedure, and the escape of the air subsequently has in all his cases been followed by a natural passage from the bowels. Where great pain existed, or where much struggling was caused by the mode of treatment, Dr. Cheavle employed chloroform, and in one case administered one drop of laudanum.

PHYSIOLOGICAL TREATMENT OF CHOLERA.

PROF. SEMNOLA believes that we have as yet no means of destroying the cholera bacillus in the organism, and also that the heroic treatment of the premonitory, or algid stage, is extremely dangerous. He, therefore, advises a mode of treatment which he describes as physiological.

This treatment consists in absolute rest of the whole organism, and especially the digestive organs, from the time of the first manifestation of diarrhoea.

In six thousand cases at Naples in a late epidemic, it was observed that the giving of a few teaspoonfuls of bouillon after the first attack was sufficient to cause a severe relapse. Nourishment when taken should be in the form of milk.

The preservation of bodily strength the author thinks most important, and seeks to accomplish this by warm baths. Given in the first stage of cholera they relieve visceral congestion, promote elimination through the skin, and exercise a tonic influence on the nervous system. After the bath the patient is wrapped in woollens, and given warm, aromatic, and alcoholic drinks.

Opium in small doses is the only drug the author considers useful.—*Medicinisch-Chirurgische Rundschau*, No. 20, 1886.

BORACIC ACID AS A LOCAL ANTISEPTIC.

DR. A. C. EWING states in the *American Practitioner and News* for November 13, 1886, that he has recently used boracic acid in the treatment of a deep suppurating wound in the palm of the left hand, which had been inflicted two weeks previously, and was now suppurating tolerably profusely. The patient's hand was in a semiflexed position from the involuntary contractions of the tendons and fascia, and was the seat of extremely acute pain. He employed about 30 grains of powdered boracic acid, dissolved in a half-ounce of water, and applied on a pad of absorbent lint. The patient reported that this application entirely freed him from pain, and the wound could be freely manipulated without causing the patient any suffering. Dr. Ewing states that he is still using the same dressing, applied once daily, on account of its excellent antiseptic qualities, and that the wound is healing rapidly by granulations, and that the necessary manipulations required to overcome the stiffness of the tendons and fascia could be employed without causing the patient pain.

THE ACTION OF SOLANINE.

This substance, discovered in 1821 in France, is obtained from potato-shoots and also from the parings of very young or very old potatoes. It becomes glucose when treated by some of the acids, and this change

is thought to occur in the organism under the influence of gastric juice.

With acids it forms salts.

Although known for many years, it has been neglected by therapeutists.

DR. GENENIL has given it in doses from $\frac{3}{4}$ of a grain to 5 grains three or four times daily. He commonly orders 3 grains in grain-doses. He does not hesitate to give 6 or 8 grains daily, if needed. It may be given in capsules or hypodermically, also upon a denuded surface or by inunction with fats. The author considers solanine a narcotic to the medulla, spinal cord, and nerve-trunks, and paralyzant to the terminal ends of motor and sensory nerves.

It may be given without danger in large doses; it does not have cumulative effects; it has none of the inconvenient after-effects of morphine or atropine.

It does not produce cerebral congestion, and so may be given to the aged and to children; its use is indicated wherever we have to combat excitement, spasm, and pain. The author's best results were obtained in the treatment of sciatica.—*Bulletin Général de Thérapeutique*, vol. iii.

IODINE IRRITATION.

The external application of the tincture of iodine made with a badly-rectified spirit, containing acetone, may be followed by great irritation of the epidermis, or even vesication, and similar results may occur when a preparation of good quality is used on a susceptible patient. M. CARLES points out that the irritation may be removed immediately by the application of alkalis and alkaline salts, dilute ammonia or soda crystals being permissible where the epidermis is robust, as on the hands, whilst alkaline sulphites, bisulphites, or hyposulphites are preferable for more delicate skin. But the best agent, in M. Carles's opinion, is sodium sulphydrate, an aqueous solution containing from one to ten per cent., according to circumstances, giving relief in a few minutes. It may also be used for removing iodine stains.—*Pharmaceutical Journal and Transactions*, October 30, 1886.

THE ALKALOID OF THE TULIP.

GERARD has isolated from the garden tulip the body tulipine, which is furnished by all portions of the plant. Its chemical and physiological properties are allied to colchicine,

scillitine, and veratrine; it forms with acids crystalline salts. Its formula is not yet known.

$1\frac{1}{2}$ grains is a fatal dose for a cat, death occurring from cardiac paralysis.

In medicinal doses of $\frac{1}{12}$ and $\frac{1}{8}$ of a grain it increases the secretion of saliva, and is diuretic and laxative.

Its effects upon the brain and spinal cord resemble those of colchicine and veratrine, the latter of which is a poison to the nervous system, while the former affects principally the heart and digestive tract.

DR. NICOT has found the action of tulipine to resemble not only that of veratrine and colchicine, but also that of strychnine.—*Les Nouveaux Remèdes*, November 24, 1886.

TREATMENT OF TYPHOID CONDITIONS BY BENZOIC AND SALICYLIC ACIDS.

According to the Paris correspondent of the *British Medical Journal* (October 23, 1886), at a recent meeting of the Société Médicale des Hôpitaux, M. ALBERT ROBIN proposed a new method of treating typhoid conditions in which the organism is always overcharged with the incompletely oxidized residues of nutrition. These residues were eliminated with difficulty, owing to the fact that they are but slightly soluble in the fluids of the human body. There were certain pharmaceutical substances which combine with the nitrogenous residues of the human organism, and rendered them more soluble, and this facilitated their elimination. The principal agents which acted in this way were benzoic and salicylic acids, which, after combining with nitrogenous substances such as glyocol, passed into the urine as salicyluric and hippuric acids. M. Robin, in his first experiment, studied the physiological action of benzoic acid on combustible substances. He administered benzoic acid to persons in good health, whom he had previously dieted for a few days. Under the influence of this treatment the solid constituents of urine slightly decreased, and there was also a smaller proportion of urea, consequently its relative proportion to solid matter was lower. These results could not be attributed to a moderating action of benzoic acid on combustion, but to the action of the acid in carrying away into the urine part of the combustible substances. On another occasion M. Robin administered benzoic acid to five patients with typhoid fever, in whose urine he noticed an increase in the weight of urea and solid matter. Salicylic acid and

salts gave the same results, as also did substances such as toluene, zylene, toluic acid, ethyl, and propylbenzine, which, in passing through the system, become transformed into benzoic acid.

TREATMENT OF ANAL FISSURE.

DR. CREQUY proposes to treat this affection by introducing within the fissure a fragment of lint soaked in a solution of chloral, 1 to 50. This application is made after the morning stool, and is expelled on the following day, when the bowels move. Its action as a stimulant to granulations and a local antiseptic has been most happy.—*Les Nouveaux Remèdes*, November 24, 1886.

SUBMUCOUS INJECTION OF LACTIC ACID FOR THE CURE OF THE EARLY STAGE OF LARYNGEAL PHTHISIS.

At a recent meeting of the Medico-Chirurgical Society of Montreal (*Medical News*, November 13, 1886), DR. GEORGE W. MAJOR, in a short paper, related his experience of lactic acid as a local application in the ulcerative stage of laryngeal phthisis. He said that it was probably the most speedy and most efficacious plan of treatment yet introduced. Ulcerations healed under it most kindly, and tuberculous deposits underwent absorption more rapidly than by any other means. But it was of lactic acid employed as a submucous injection into the substance of the laryngeal tissues that he wished to speak. In the early swellings and œdemata it had rendered very remarkable results in Dr. Krause's (Berlin) hands. Dr. Major had the privilege, during the past summer, of seeing many of Dr. Krause's cases, and he was happy to be able to endorse all that had been maintained by Dr. Theodore Herring, of Warsaw, and Dr. Krause in its favor when used as an injection. Dr. Major employed a twenty to thirty per cent. solution of the remedy, and inserted at one sitting from fifteen to twenty minims of the liquid. Very trifling pain followed, and but little after-irritation was induced. The swellings disappeared in periods varying from twenty to thirty days, and ulcerative changes were avoided. A case undergoing treatment by injection was exhibited to the members of the society, and the result was deemed very satisfactory and encouraging. Dr. Herring's syringe, as modified by Krause, was the instrument employed for the injections. Alto-

gether, Dr. Major regarded the lactic acid treatment of laryngeal tuberculosis as the greatest advance yet made in the treatment of this disease, and looked forward to a great future for it.

TURPENTINE IN CHRONIC DISEASES OF THE RESPIRATORY ORGANS IN CHILDREN.

DR. DESCRAIZILLES describes several cases where the diagnosis lay between chronic bronchitis and tuberculous infiltration, with the physical signs of cavities, in which turpentine produced very beneficial results.

In the *Revue Mensuelle des Maladies de l'Enfance* the author describes the preparation which he uses as a solution in alcohol or water of turpentine which is "hydrated,"—has been long exposed to the air. He commonly used the following formula:

Turpentine, grs. xxx;
Alcohol, f3x;
Water, f3v.

A quantity not exceeding 9 grains of the solid daily gave excellent effects. In omitting alcohol from the solution at least 6½ ounces of water will be required to 15 grains of the solid, and it is then advisable to add an astringent syrup. Such solutions are best given at meals.

The effects were the rapid lessening of foul expectoration and a tonic influence upon digestion.

ŒDEMA OF THE PREPUCE.

DR. J. G. TAPPER writes to the *New York Medical Journal* for November 6, 1886, that for several years past he has been treating very successfully the great œdema and infiltration attending many cases of phimosis and paraphimosis as the result of congenital or specific causes. In many cases occurring in the adult we find a perfect horror of being confined to the bed. In fact, unpleasant circumstances connected with the trouble render it imperative that our patient should engage in his usual occupation during the treatment. These requirements have led him to the adoption of the following measures: He saturates a given quantity of absorbent cotton with chemically pure glycerin in which bichloride of mercury has been dissolved in proportions varying from 1 in 1000 to 1 in 5000, according to the amount of fœtor present; or, in place of the bichloride, iodoform, carbolic acid, or any antiseptic agent preferred

may be used. With the cotton so charged he completely encircles the organ so far as it is involved. Over this a large rubber condom is drawn, which is then suspended from an abdominal band. This dressing is to be repeated every six hours until the oedematous condition disappears. At that time a beginning pallor will be observed, and often in from twelve to twenty hours the prepuce will have become very pale and shrivelled. The great majority of cases yield promptly, and no further progress is observed after the first application. If ulcers are present, it will often be discovered that they have taken on a healthy action before it has been possible to expose them, and not infrequently this progresses until the cure is completed. The advantages of this dressing are: It is cleanly; there is no difficulty in applying it, patients frequently continuing the treatment at their rooms or places of business after the first dressing; it does not expose or confine the patient; and the results in his hands and in those of others who have tried it at his suggestion, have been very satisfactory.

THE INFLUENCE OF COCAINE UPON THE SKIN.

HERZOG has reported (in the *Münchener Med. Wochenschrift*, No. 13) that pencilling the intact skin with ten and twenty per cent. solution of cocaine has no effect whatever. He therefore employs the galvanic current, as recommended by Wagner, and uses as anode an electrode constructed by Stintzing, in which the fluid—the cocaine solution—serves directly to conduct the current. This anode is generally placed upon the forearm, and an ordinary electrode taken in the hand of the opposite side. Galvanic current and cocaine together produce anæsthesia. To increase this the strength of both agents must be increased together. A gain in intensity is, however, no gain in duration. This method has no result upon deeper tissues.

Upon a thinned or denuded skin the ordinary injections and applications are useful, especially to painful excrescences. Urticaria was cured by a ten per cent. solution.

Cocaine is a vigorous agent in rendering the skin anæmic.

TREATMENT OF SUBSTANTIVE EMPHYSEMA.

DR. FRANCIS DELAFIELD read a paper on the "Treatment of Substantive Emphysema" before the New York Academy of Medicine.

For the chronic interstitial pneumonia which so often attends the disease he suggested change to an out-door life in a favorable climate, total abstinence from alcohol and tobacco, and partial abstinence from sugars and starches. Iodide of potassium, iron, and cod-liver oil might, by improving the general health, delay or modify the progress of the disease, without any specific action upon it. He also recommended the inhalation of compressed air, and the expiration into rarefied air, to make the pulmonary circulation more active, and thus bring about a change for the better in the nutrition of the lung-tissue. He had more frequently used compressed oxygen gas with real benefit.

The *constant dyspnœa* he thought arose from thickening of the walls of the air-cells and bronchi, with dilatation and congestion of the blood-vessels in the stroma of their mucous membranes; also from chronic endarteritis, rigidity and contraction of the walls of the arteries; also from dilatation and hypertrophy of the right ventricle; all interfering with the circulation. The sudden attacks of dyspnœa were due to contraction of the pulmonary vessels, which disappeared after death, as they could then be injected readily.

The remedies were those already enumerated, and drugs known to diminish arterial tension, such as iodide of potassium, chloral hydrate, belladonna, stramonium, and opium.

Some of the severest asthmatic attacks came from spasmodic contraction of the bronchi. The remedies were the inhalation of the fumes of stramonium and nitrate of potassium, chloroform and ether; the use of emetics, belladonna, the compound spirits of ether and opium.

For the venous congestion of the stroma of the mucous membrane, which is often so great as to make it resemble erectile tissue, the remedies are those which cause a large and rapid exudation of mucus from the bronchi, such as lobelia and *grindelia robusta*; the rapid determination of blood to the skin by means of dry cups, and such drugs as stimulate the heart, like caffeine, convallaria, and digitalis.

For the spasmodic contraction of the smaller branches of the pulmonary artery, which causes so much distress in this disease, as it also does in angina pectoris and in uræmic attacks, we must use the remedies which quickly diminish arterial tension, such as amyl nitrate, chloral hydrate, potassium iodide, and opium.

Chronic bronchitis is a very important feature in many cases of emphysema. It is

more apt to be favorably affected by change of climate and mode of life than by drugs.

For the general venous congestion, loss of nutrition, and anæmia the indications seemed to be to use cardiac stimulants, such as caffeine, convallaria, and digitalis; to improve the nutrition by iron, oxygen, and fats, and change of climate.

DISCUSSION.

DR. WM. H. THOMSON thought there was bronchitis in all cases, and this was generally caused by chills of the skin from too thin clothing: flannel, or even buckskin, should be worn from November to June of each year; thick shoes, woollen stockings, sleeping in flannel in the winter-time, etc.

The next great cause was the excessive use of meat in this country, viz., meat three times a day, or with all the meals. The nitrogeous wastes irritated the blood-vessels, especially of the lungs, kidneys, and other organs, producing general sclerotic disease, with thickening of all the arteries and excessive growth of new interstitial connective tissue. He believed, next to change of climate, an emulsion of linseed-oil was the best remedy for the bronchitis, although it was true that chloral and morphine were generally added to it. Linseed-oil was the best of all expectorants. For the sclerosis and excessive growth of connective tissue he thought small doses of corrosive sublimate more useful than iodide of potassium, when aided by light diet, such as milk, koumiss, fish, vegetables, fruits, etc.

Nitro-glycerin was a good palliative, and sometimes more: it not only lessened arterial tension, but raised the specific gravity of the urine, and cleared the blood of many waste and irritating products. Arsenic was another useful remedy; it, phosphorus, corrosive sublimate, and cod-liver oil all produced fatty degeneration, softening of sclerotic tissue, and thus aided their absorption or removal.

DR. GEORGE L. PEABODY agreed with Dr. Delafield in almost all his views, and thought his symptomatic treatment admirable. He disagreed with those who supposed that iodide of potassium or any other remedy could act as a resolvent of hardened and thickened connective tissue, except in syphilitic cases.

DR. KINNICUTT thought that spasm of the small vessels played as large a rôle clinically as claimed for it by Dr. Delafield. He believed that nitro-glycerin was even more useful in chronic and persistent dyspnœa than in acute spasmodic attacks. He gave it internally in small doses three times a day, and was satis-

fied with the relief caused by it. Chloral and the iodides were also useful.

DR. PUTNAM JACOBI laid stress upon the value of compressed air, and cited cases relieved by it. It neutralizes the dead residual air which remains in such large quantities in the air-cells and smaller bronchi in cases of confined sclerosis and emphysema of the lungs; also the retained carbonic acid gas, which is such an important irritative cause of the growth of new connective tissue.

DR. J. PETERS, the Chairman, called attention to the iodide of ethyl, which has a larger quantity of iodine in it than any other preparation. If the iodine in the iodide of potassium is the active agent, then iodide of ethyl must be still more useful. It is volatile, and may be used for inhalation, like nitrite of amyl and nitro-glycerin, and may also be taken internally. Whatever the theoretical views may be about it, it certainly is a very useful remedy in emphysema. It has an anæsthetic action when inhaled. It is absorbed into the blood, decomposed in the body, and excreted as iodide of potassium. It has been given internally in doses of 2 to 5 decigrammes, or 3 to 8 grains, in scrofula, obstinate catarrhal and rheumatic affections, and in cardiac dropsy. Its chief use, however, according to Brunton and others, is as an antispasmodic in asthmatic paroxysms, either of the purely spasmodic kind, or occurring in chronic bronchitis and emphysema, or in cardiac or laryngeal disease. In some cases it gives very great relief, and not only cuts short the paroxysm, but benefits the bronchitic condition.

Muriate of ammonia has a great reputation in Germany in the resolution of thickened and sclerosed tissues. Dr. Peters sincerely hoped that this might be so, and was inclined to sympathize with those who claimed the same for phosphorus, arsenic, and corrosive sublimate. He was an optimist in medicine: there were so many powerful drugs which produced such manifest changes in the functions and tissue metamorphoses of the body, that it seemed as if we at some time, and hopefully not in the far-distant future, would learn how to apply them successfully even in the cure of some organic diseases.

He also called attention to nux vomica as a great heart tonic, often useful when digitalis, caffeine, and convallaria had failed. It was also useful in emphysema in compensating the weakness of the respiratory muscles which often prevailed, and which so often caused chronic dyspnœa. It would have to be avoided in spasmodic attacks, in which, and

spasm of the blood-vessels, he suggested conium as the most powerful paralyzer of muscular action that we were acquainted with.

Reviews.

MANUAL OF OPERATIVE SURGERY. By Joseph D. Bryant, M.D.

New York: D. Appleton & Co., 1887.

The work of Prof. Bryant, while it does not pretend to be a rival of the larger works or systems of surgery, is of its kind a most excellent book. Theories and doubtful methods of operating find no place in the volume. It is rather to known facts and established procedures that the author has limited his labor, and the judgment which he evinces in selecting from the various methods of operating in surgical cases is generally of a most reliable nature; indeed, it is this selecting from many proposed procedures, which are usually met with in the larger surgical works, that much of the value of Prof. Bryant's book depends, and in this respect the book becomes a very able aid to the unexperienced surgeon. The scope of the work includes most of the surgical diseases, and the operative methods for their relief or cure. The operations peculiar to the female sex, and the surgery of the eye and ear, are not considered in the book.

Chapter i., which discusses "General Consideration," or what may be termed the technique of surgical operations, is a most valuable one. The various rules and suggestions which are found here are evidently the outcome of a large experience and an observing surgeon. A careful study of this section of the book will undoubtedly tend to perfect operative surgery, and a faithful carrying out of the various methods proposed must certainly give more satisfactory results than would otherwise be obtained; since it is very often just this attention to seemingly small matters that determines the favorable termination of an operation, and a neglect or careless performance of minute details may frequently defeat the successful result of the surgeon's labor.

The chapter on "Agents for Controlling Hemorrhage" is all that could be desired, being very complete, and fully represents all the advances of modern surgery. It is with much satisfaction that we find the author an advocate of the catgut ligature for ligating arteries of every size, and with him we have never had occasion to regret their employ-

ment, believing they offer the same amount of security against accidents as any other variety of ligature.

Chapter iii., on the "Treatment of Operative Wounds," is a most important one, and treats of that department of surgery which, of all others, is at the present time claiming more attention from surgeons than any other. The question to be settled, if it is not already decided, is that of antiseptic surgery. Much has been written pro and con of this subject, and it is yet not finally, or at least universally, agreed upon who are in the right. Prof. Bryant, it gives us much gratification to say, is another to be added to the list of those who advocate the adoption of antiseptic measures in the dressing of wounds after operation, and the rules he gives in order to accomplish this end are those which may be adopted with every probability of success.

Chapter iv. treats of the "Ligature of Arteries," and the directions given for performing this operation upon the different arteries are brief, but in no way deficient in the necessary information to successfully ligate any vessel, provided strict attention is given to the author's rules. The illustrations which are given under this chapter are unusually good, and will greatly aid one in the study and practice of this operation.

"Operations on Veins, Capillaries, etc." This chapter considers ligature of veins, and the very proper advice is given to ligate these vessels, when of any size, if divided during the course of an operation. The advisability of securing the borders of a partly divided large vein with catgut is thought to be a questionable procedure, notwithstanding it has been recommended by many writers, and the danger of secondary hemorrhage believed to be much greater than if the vessel is tied above and below the wound in its walls. The operation of excision, crushing, and ligaturing for hemorrhoids is described, the preference being given to the ligature. Having had occasion to perform this operation quite frequently, and having taken the opportunity to employ the several methods proposed by different writers, we have, from our experience, decided upon the crushing operation with the cautery, since the results both to ourselves and patient have, we think, been much more satisfactory than when other methods have been employed. The operation by injections of carbolic acid or astringents has in our hands not proven itself very satisfactory. The author also cannot recommend it, and the occasional bad results—abscesses, gangrene—

which may follow its use should make us hesitate to employ it. The operations for varicocele, venesection, transfusion, and nævus are also given in this chapter.

Chapter vi., on "Operations on the Nervous System," in which the operation of trephining is given, and Prof. Bryant thinks it is one which is more often performed than the requirements of many cases warrant. From our experience in this class of cases we have formed rather the contrary opinion,—that is, there has been a neglect on the part of the surgeon, and the operation has been postponed until too late, or not performed at all. To consider the opening of the skull cavity as a trifling surgical operation, one that may be compared with the amputation of a phalanx in severity, as has been done, we believe to be rash and dangerous surgery, but by employing every care, and the use of every antiseptic precaution, the operation is generally not followed by any unfavorable results. Cerebral localization as a means of diagnosis in head injuries has also received the attention of the author, and its importance in assisting the operating surgeon indicated. Division, excision, and stretching of the nerves are included under this chapter; and it is advised, when possible, if excision be done, not less than two inches in the continuity of the nerve should be removed. The suturing of divided nerves is recommended, its results being in every way favorable, while the practicability of nerve transplantation is as yet thought to be undetermined.

The chapters devoted to "Operations on Tendons, Fasciæ, Muscles, and Bones" are well written, and include all that modern operative surgery has advanced to benefit these lesions. More especially is this to be noticed under the various operations which have been proposed and done for the different bone lesions. Amputations are described in full and profusely illustrated, making a very valuable chapter on this important division of operative surgery. Under deformities we should have liked described the method of applying the plaster-of-Paris jacket by means of the hammock for curvature of the spine, in addition to the method of suspension of the patient; since the former is quite as efficient and much more comfortable to both patient and surgeon in its application, more particularly may this be said in regard to young children. Plastic surgery is very thoroughly described, and numerous cuts are given to illustrate this division of operative surgery, which greatly facilitate one to understand the

various methods proposed for the relief of the lesions in which such operations are necessary. A chapter is devoted to "Operations on Hollow Viscera in Contact with Serous Surfaces," and includes, among others, those operations which may be performed upon the intestinal tract, and those in connection with the kidney, spleen, and hernia. The operations on the anus and rectum have received due attention.

The chapter on "Operations on the Urinary Bladder" describes catheterization, aspiration, cystotomy, and digital exploration of this organ. Lithotomy, litholapaxy, and lithotomy are also fully described. An instrument, devised by the author, combining both a crusher and evacuating-tube, to be employed in removing the last fragments after the larger instrument has been used, or to remove a very small calculus, seems to us a most useful and valuable accessory to the mechanical appliances that may be utilized in performing the crushing operation.

Chapter xvii., on "Operations on the Penis and Scrotum," discusses those for hydrocele, and preference is given to incision with excision, while injection of the sac is also spoken highly of. In the employment of the tincture of iodine for the latter purpose the author directs it to be diluted with three or four parts of water. This we believe to be a mistake, and in our practice we invariably use the undiluted tincture; the result has always been satisfactory; indeed, so much so that for the past few years we have entirely confined ourselves to its use in the treatment of this lesion. The operations for "congenital malformation of the urethra" and for "acquired urethral defects" are in no respect deficient, and represent very completely our knowledge on these subjects. External and internal urethrotomy are briefly described, and, in regard to the latter, Otis's operation has received a full description, from which we would infer that the author regards it favorably, and to speak of our own experience of this method of treatment of urethral stricture, we have had a successful result in every case in which it has been employed, and we are inclined to consider the operation the best yet advanced for this lesion.

The concluding chapter of the book is headed "Miscellaneous Operations," and includes, among others, extirpation of the breast, tracheotomy, operations for ganglion, wiring of bones for compound fractures and fracture of patella, etc.

In concluding our notice of Prof. Bryant's book, it remains for us to congratulate him

upon the successful result of his labor. He has written a very able and reliable surgical work, one that may be consulted both by surgeon and student, and one that contains all the more important advances of modern surgery. The publishers' part of the work has been well done, and the numerous illustrations add much to the value of the volume.

J. H. C. S.

THE SURGERY OF THE PANCREAS, AS BASED UPON EXPERIMENTS AND CLINICAL RESEARCHES. By N. Senn, M.D.

The above pamphlet is a reprint of Dr. Senn's essay read before the American Surgical Association, April, 1886, and in which, as stated by the writer, "an attempt will be made to lay the foundations for a rational method of treatment of some of the injuries and diseases of the pancreas by direct surgical measures." This study begins with the anatomy of the organ; in fact, its development and also its physiological function. Experimental investigations were made in order to ascertain the tolerance of the pancreas to direct treatment, and also with the object "to elucidate some of the causes and pathological conditions of some of the well-recognized lesions of this organ." Traumatisms are considered under contusions and wounds, both penetrating and gunshot. Acute and chronic inflammation of the pancreas, also gangrene and abscess, are quite fully described. Hemorrhage of the pancreas, including hemorrhagic cysts and diffuse hemorrhage, have received attention. Cysts of the pancreas, and tumors of the pancreas, including hypertrophy, sarcoma, and carcinoma, are treated of by the author, and finally a consideration of tuberculosis, lipomatosis, and lithiasis of the ducts of the pancreas terminate the work.

THE MECHANISM OF INDIRECT FRACTURES OF THE SKULL. By Charles W. Dulles, M.D.
Philadelphia: P. Blakiston & Co., 1886.

This brochure by Dr. Dulles discusses, and very ably endeavors to determine, the mechanical law which influences indirect fractures of the skull. That portion of his essay which relates to the historical part of his subject is an evidence of much research, and we feel indebted to him for arranging it together in such a readable form. In order to satisfactorily present his subject, Dr. Dulles has studied it under the following heads: "Elastic Properties of the Skull," "Anatomical Peculiarities of the Skull," "Architectonic Peculiarities of the Skull," "Influence of Soft Parts and Contents of the Skull," and finally "Study of Cases." The conclusion arrived at by the author is that the "bursting theory" has more to recommend its acceptance than any other; indeed, he believes it to be sustained by "reasoning, experiment, and clinical observation."

liarities of the Skull," "Influence of Soft Parts and Contents of the Skull," and finally "Study of Cases." The conclusion arrived at by the author is that the "bursting theory" has more to recommend its acceptance than any other; indeed, he believes it to be sustained by "reasoning, experiment, and clinical observation."

OUTLINES OF THE PATHOLOGY AND TREATMENT OF SYPHILIS AND ALLIED VENEREAL DISEASES. By Hermann von Zeissl, M.D. Revised by Maximilian von Zeissl, M.D. Translated by H. Raphael, M.D.
D. Appleton & Co., New York, 1886.

The influence of the Vienna school over Germany, and the entire medical world, has during the past twenty or thirty years been of a very decided and positive character, and in no special branch of medicine has this influence been greater than in that relating to the subjects treated of in the above volume. The names of Sigmund, Hebra, and Zeissl must ever remain in the foreground as investigators, writers, and teachers upon the various lesions resulting from venereal diseases. The translation of Prof. von Zeissl's work we consider to be a most valuable addition to English medical literature, and congratulate the translator upon the faithful and most excellent rendering he has given us; indeed, we have not noticed, in a careful reading of the book, any serious errors or obscure passages, which are so liable to occur in a translated work.

The book is divided into three sections, which treat respectively of gonorrhœa, soft chancre, and syphilis. The section devoted to syphilis occupies about two-thirds of the volume. An introductory chapter on "The Venereal Contagions" gives a brief *résumé* of the opinions held by the authors upon this very important subject. It is here stated the belief that there exists two kinds of poisons, separate and distinct, one for the chancre and one for the chancroid. Semen is thought to be a probable carrier of the virus. Why all syphilitic parents do not beget syphilitic children is said, as yet, not to have been determined. The discharge from a chancroid upon a syphilitic person inoculated upon a non-syphilitic is stated always to result in a chancroid only. Syphilitic inflammatory lesions, papules, nodules, etc., when irritated by implanting upon these chancroidal secretion, are said to be capable of causing the primary lesion of syphilis when inoculated upon a non-syphilitic individual. Mixed chancre, such as described by the Lyons school, has been discarded long ago. The syphilitic pri-

mary lesion (chancre) is believed to be the first manifestation of general, constitutional syphilis. We have selected the above principles from those given by the authors in order to show the views which they hold upon the points that are still disputed by writers upon these subjects. When it is remembered that the opinions here given are based upon many years of observation, and an experience in treating this class of affections seldom, if ever, exceeded by any, their value must necessarily be very great, and a denial of their correctness received with hesitation.

Gonorrhœa is defined as "a catarrh of the urethral mucous membrane," and a differentiation of the disease is made into a serous, epithelial, or mucous, and a purulent gonorrhœa, although a distinction between these varieties cannot always, it is said, be strictly maintained. The serous and mucous forms are forerunning stages of the purulent catarrh of gonorrhœa, and it is thought that the disease may be arrested at any one of these stages.

While it is admitted that gonorrhœa is undeniably a disease that may be transmitted from one person to another, the views as to the nature of the infecting agent are not considered by the authors yet sufficiently clear as to positively determine what it is. The possibility of occasioning a purulent secretion in the urethra by means of mechanical, chemical, and pathological irritants is not denied, being, it is said, "a matter of daily observation;" and, indeed, Von Zeissl does not stop here, but goes further, and writes as follows: "In our practice, however, we have seen numerous instances where men troubled only with the prodromal phenomena of gonorrhœa—*i.e.*, a prickling sensation at the meatus urinarius, where not a trace of pus could be found in the urethral discharge—infected their wives and mistresses. We have likewise had the experience that the slight mucous secretion of gleet is capable of communicating a gonorrhœal disease." The conclusion reached from their experience and investigations upon this subject is "that the morbid potency of a gonorrhœal infection is not to be found in the pus-cells, but in a specific catalytic power of the secretion,—*i.e.*, in a contagion which adheres to the epithelial as well as the pus-cells, and which we are not able to isolate any more than other kinds of contagion. The hypothesis that an animal or vegetable parasite (Neisser's gonococcus) forms the basis of a gonorrhœal contagion has not yet been satisfactorily demonstrated." This view of the question we

do not think is one which very materially helps us out of the difficulty. To say the agent of contagion is a "specific catalytic power" tells us nothing. The hypothesis of the gonococcus is much more satisfactory, but, unfortunately, we, with the authors, have not as yet been convinced of its etiological nature. From our own experience, and from the present state of the scientific investigations upon this subject, we are inclined to the pus infection as the genetic factor in this disease, and opposed to any theory which depends upon a specific element as a causative agent.

Prophylactic measures against gonorrhœa the authors, very properly, we think, believe are all uncertain, and they can only recommend thorough washing with water, and urination directly after copulation, as a possible preventive against infection. In regard to the abortive treatment of gonorrhœa, its accomplishment is considered beyond our present ability, and the methods which have been suggested are thought to be often positively injurious, without any beneficial result.

The treatment of gonorrhœa by the authors is such as we can fully endorse, both from its simplicity and efficacy. Local methods, by means of injection, are preferred to internal medication, but it is not to be forgotten that "most cases of gonorrhœa would get well within four or six weeks without injections or internal medication," therefore, we think, in many cases, treatment has received credit due to nature. The sections which discuss the various complications that may arise during an attack of gonorrhœa are very satisfactory, giving the symptoms, diagnosis, and treatment of these lesions in a concise and practical manner. The same may be said of the section devoted to gonorrhœa in the female.

The soft chancre or chancroid is defined as an ulcer, the origin of which is ascribed to a contagious specific matter. In regard to the nature of the specific matter, it is said, "we know no more regarding the contagious element which is capable of giving rise to soft chancre than we do of the nature of contagions in general." Here, again, we have the etiological factor being referred to a specific element; and, again, we are not willing to accept this view, since all the difficulties of believing in what we cannot demonstrate may in a great measure be removed by simply looking upon the chancroid as a non-specific ulcer, occasioned by an irritant, *viz.*, pus. Experimental investigations and pathological lesions apparently sustain the latter

view, while, on the contrary, no investigations have, as yet, been able to show any specific organisms in etiological relation with this disease, nor is it possible to differentiate between many pathological lesions, resembling the chancroid, but of known origin, of a non-specific nature.

The plan of treatment for chancroids advised by Von Zeissl is a most excellent and efficient one, which we have most faithfully tested for the past three or four years. Its success depends upon its simplicity, and non-interference with the healing process; therefore all irritants and caustics are to be avoided, but cleanliness and protection of the lesion practised. In a word, the chancroid we think should be treated in reference to the local condition of the sore. Thus, when normal, if such a term is ever applicable to a pathological process, cleanliness and protection; when irritable and painful, soothing applications and anodynes; when indolent and stationary, stimulants, and even cauterization.

The section on "Syphilis and its Different Lesions" is a very complete outline of this disease; indeed, in many cases the term outline does not sufficiently express the scope of the work, since frequently it would be difficult to more fully describe the lesion under consideration than has been done by the authors, and where descriptions have been somewhat briefly given, we find nothing of importance has been omitted, so that for the practical physician we know of no better work for reference or study.

In regard to the nature of the virus of syphilis, Von Zeissl believes it to be a "fixed principle," which, as yet, has neither been discovered by the microscope nor chemistry. The claim to the discovery of a peculiar micro-organism in the blood and morbid lesions, which is the cause of syphilis, has not yet been confirmed in the author's opinion. The first manifestation of the presence of the syphilitic virus is said to be at the spot where it was deposited and absorbed, and the various appearances presented by the local lesion is thought to depend upon the nature of the vehicle in which the virus is contained, —i.e., pus, ichor, or with some non-irritating fluid, such as blood, serum, or lymph. When the vehicle is irritating there results ulceration and suppuration; but when the fluid is of an opposite nature, and there is no deep solution of continuity at the place of infection, there occurs no suppuration or ulceration, and a rapid healing of the excoriation, the characteristic induration of the constitu-

tional disease appearing later. The value of the auto-inoculability of an ulcer upon one affected with it is believed to be of little diagnostic importance, since pus of non-venereal origin will produce on syphilitic persons a series of inoculable ulcers. Much has been written upon the way in which the virus of syphilis gains access to the system, some claiming that the blood is the means of conveyance, others the lymph, and at the present time both have their advocates. We are in accord with Von Zeissl, who says "that the syphilitic virus is conveyed to the blood by the lymphatic vessels," and we think the course, symptoms, and history of the disease fully sustain this view. The various lesions which may result from syphilitic infection, and the different organs and structures of the body which may be attacked by the disease, are most ably described. The same may also be said of hereditary syphilis and its lesions.

The great experience of Prof. von Zeissl, and the unusual opportunities he has had in the treatment of syphilis, lead us to turn to this portion of the book with much interest, in order to learn his opinion upon this most important division of the subject. Here we find the authors are at variance with most English, American, and French syphilographers in that they do not place the same value upon the mercurial treatment of this disease, but the expectant or iodine treatment is advised. It is believed "that when mercury is employed very early—as soon as the primary lesion is detected, or the first eruption appears—the symptoms then present will, it is true, speedily disappear; but obstinate relapses are more likely to follow than when syphilis is first allowed to spend its fury." Therefore it is seen that the objection to this drug is its too early employment. Thus, it is stated "that it is not the mercury that is injurious, but the improper time chosen for employing it against syphilis." Indeed, so strongly is this opinion held by the authors, that they do not hesitate to write as follows: "Syphilitic patients who are mercurialized very early, especially before general phenomena have appeared, are oftener attacked by grave lesions of syphilis (cerebral and visceral), and they are oftener subject to relapses than those who, for a long time, were not treated at all, or first with iodine and later on with mercury." And, again, when treating of the predisposing causes of syphilis of the nervous system, "the too early use of mercury" is enumer-

ated among others. The time when mercury should be used, according to the authors, is only after the expectant and iodine methods have failed. To better understand their treatment of syphilis, we give a brief outline of the plan they advise. Thus, a patient affected with a chancre, and having no constitutional symptoms, the treatment is confined to the local lesion. When the syphilitic skin-lesions appear, either macular or papular eruptions, nothing is given, unless, at the end of eight weeks, there is no improvement, or it has not entirely disappeared, they then prescribe iodine preparations. If eight weeks more are passed, and the symptoms of the disease have not entirely disappeared, "then the treatment with mercury may be resorted to without any fear concerning the future course of the disease." The conclusions arrived at by them, in following out their plan of treatment in regard to the expectant method, are, "that constitutional syphilis will follow, even if not a particle of mercury is used, and that the assertion of anti-mercurialists, that the so-called secondary and tertiary syphilis are only the manifestations of the mercurialization, is not true. Relapses and the gravest forms of syphilis may supervene just as well after a strict and scrupulously carried out expectant plan as after an anti-specific treatment. We only wish to say that these phenomena occur comparatively rarely after expectant treatment, and that the relapses are apt to occur less often than after an early mercurial treatment." And for the iodine treatment they write, "Iodine in proper quantities, in conjunction with a carefully regulated regimen, are sufficient to cause the symptoms of syphilis to disappear, or at least to be weakened, so that only a few mercurial inunctions will be necessary to complete the cure, without fear of a relapse occurring in years to come." Notwithstanding this method of treating syphilis has the endorsement of such high authorities as our authors, we fear it will not be adopted by many American physicians, who have been brought up to believe in the almost specific effect of mercury in this disease, and who, in their experience, have undoubtedly seen good results follow its employment. However, as previously remarked, the great experience and unusual opportunities of the authors to investigate this disease in all its stages make us hesitate to oppose their conclusions, and we can only say our experience in the opposite direction, viz., first mercury and later iodine, has given satisfaction.

J. H. C. S.

THE JOURNAL OF COMPARATIVE MEDICINE AND SURGERY. Edited by W. A. Conklin, P.H.D.V.S., and Rush Shippen Huidekoper, M.D., Veterinarian, Alfort, and published by A. M. Hummel, M.D., 1217 Filbert Street, Philadelphia.

With the issue of the October number the management of the *Journal of Comparative Medicine and Surgery* passes into new hands. The publication office is transferred from Philadelphia to New York, and the *Journal* itself is enlarged and improved in every department. The paper and the typography are better than in its earlier issue, and the number of pages are increased and its value enhanced by the addition to the editorial corps of some of the best known and most scientific members of the medical profession. The *Journal* has assumed a more thoroughly scientific aspect than ever, utilizing, as it does, the best material from Harvard, the University of Pennsylvania, the Royal Veterinary School of Dresden, and other prominent colleges. It is the only journal published on comparative medicine and surgery, and the reputation of its editors is sufficient guarantee that this field of science will be well represented.

The October number contains a number of valuable original articles, among which we may mention "Avian Tuberculosis," by John Bland Sutton, F.R.C.S.; on "Injuries of the Beak in Birds and the Method of Repair," by R. W. Shufeldt, M.D.; the "Rôle of Microbes and their Chemical Products in the Causation of Diseases," by James Law, F.P.C.V.S.; and "Atrophic Carcinoma," by Richard W. Burke, V.S.A.V.D., and others.

ANALYSIS OF THE URINE, WITH SPECIAL REFERENCE TO THE DISEASES OF THE GENITO-URINARY ORGANS. By Hofmann and Ultzmann. Translated by T. B. Brune and H. H. Curtis. Second Edition. Appleton & Co., 1886.

The names of Hofmann and Ultzmann are so well known as those of authorities upon matters pertaining to the examination of urine and urinary disorders that the profession is ready to welcome a second edition of this very valuable treatise.

After a short introduction the writers discuss the histology of the urinary apparatus. This is treated as briefly as is consistent with the demands of the subject. The greater part of the book is devoted, as its title indicates, to the analysis of the urine and its relation to disease; and here there does not seem to be anything wanting to make it nearly complete. Qualitative examination receives careful attention, and is brought

fully up to date by the added notes of the translators. These notes—always separated by brackets from the original text—include the acetone and diacetic acid reactions; the latest methods for the recognition of levulose, lactose, peptone, propeptone, mucin, globulin, etc.; the newer tests for bile, albumen, and glucose, etc. The chemical notation is employed to explain the reactions when not too complicated.

The methods for the quantitative analysis of but a few of the constituents of the urine are given, and occupy comparatively little space. These methods are, however, reliable, and made very plain by means of illustrative examples worked out by way of explanation.

The microscopical and chemical characteristics of the urinary sediment are also ably treated, and the book is enriched by the addition of a series of lithographic plates, taken principally from the authors' atlas.

Probably the most valuable feature of the book is the attention devoted to the relation which urinary analysis bears to clinical diagnosis. Here we find, for example, a discussion of the causes which increase or diminish the elimination of urea; the different forms of renal disease producing albuminuria, and the microscopical and chemical means of determining which of these is present; the various causes of hæmaturia; the different stages of cystitis, etc. There is also a useful list of the diseases in which alterations of the urine are apt to occur.

The work is not so exhaustive as the large treatise of Neubauer and Vogel, and, while treating as thoroughly of analytical methods as some of the smaller books do, its clinical nature renders it invaluable to the practising physician.

J. P. C. G.

A LABORATORY GUIDE IN URINALYSIS AND TOXICOLOGY. By R. A. Witthaus, A.M., M.D.
New York: Wm. Wood & Co., 1886.

This little book is well suited to lie conveniently to hand upon the laboratory table. It is bound in note-book style, the backs being united at the top, and thus opening from the reader, and one side of each leaf is left blank for additional notes.

The subject-matter is arranged in a series of short numbered paragraphs, describing very briefly but quite clearly the progressive steps to be followed in an examination, the whole representing the acme of condensation. Yet even with the abbreviated words and style it is surprising how much useful matter the book

contains. The beginner, and even one more advanced in urinary work, will find in it nearly all that he really needs.

The last portion is devoted to the chemical investigation of the poisons, and contains the various tests usually employed.

The little volume has a few faults. It is a pity that, although it contains volumetric methods for the phosphates and sugar, and processes requiring as great care as does the gravimetric determination of albumen, yet the volumetric methods for urea are entirely omitted, Fowler's quantitative method being the only one given. The phenyl hydracine test for sugar has also been left out, although it is now well recognized in Germany. And, however useful it may be to know the antidotes to the various poisons, their enumeration seems rather superfluous in a laboratory guide. On the whole, the book is a useful addition to our literature, and is sure to be valuable to the physician to whom time is a great consideration.

Correspondence.

ICE-WATER ENEMATA.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—I have just read with interest an excerpt from the *British Medical Journal* of October 30, 1886, in relation to the efficacy of ice-water enemata in the collapse occurring in diarrhoea of children, and wish to add my testimony as to its efficacy in a wider field. I first used it in a case of prolapse of the rectum in acute dysentery, curing both troubles in a short time. This was a soldier in the service in 1863. In 1868, in a case of acute hemorrhoids, with prolapse of the rectal mucous membrane from acute diarrhoea, ice-water relieved all the symptoms more rapidly than any other treatment of which I am cognizant.

Especially valuable evidence is a case of acute procidentia of the rectal mucous tissue in a case of intercurrent dysentery in a patient 2 years of age, undergoing treatment by aspiration for an acute empyema after "measles." Here the pain from the rectal trouble was threatening collapse, coupled as it was with frequent dejections, which were not relieved by opiate enemata and saline cathartics. Recourse was had to ice-water enemata after each defecation, with the most gratifying results as to pain and frequency of the discharges. The livid mucous surface, as

it became chilled, was blanched in appearance, and the procidentia, or intussusception, was restored to its normal condition without any other aid.

RALPH C. HUSE, M.D.

TOXIC EFFECTS OF TEA.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—I have read with much pleasure the remarks of Dr. Davies on "The Toxic Effects of Tea" in your last issue, and I beg leave to ask him the following questions concerning some of the propositions laid down in his paper, which may prove to be of historical as well as of scientific interest:

1. When, by whom, and by what methods were theine and caffeine found not to be physiologically and chemically identical, and where is the discovery recorded?

2. Does not the physiological action of tea and of coffee in the main correspond with that of theine and of caffeine, and, if not, where is a record of the experiments to be found?

I am sincerely yours,

THOS. J. MAYS.

November 26, 1886.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—Will you kindly settle the following question,—*i.e.*, Can we have a physiological action of *any* drug not preceded by a *chemical* action of said drug?

DRS. LANGSON & SCHULZ.

AURORA, NEB., December 7, 1886.

[The answer to be given to such an inquiry as the above depends very largely upon the meaning with which the terms are employed. We should say that every functional act of the living tissue is accompanied by nutritive—that is, by chemical—changes in such tissue, and therefore by chemical action. The drug that affects functional activity must check or alter the chemical movements in the affected tissue, and we should certainly say that the drug had a chemical influence. The term physiological action is used with such various significance that before any close reasoning is indulged in it must be defined. The writer often means that the physiological action of the drug is the ultimate apparent effect which it has upon the function. Thus, the physiological action of atropine is to arrest the secretion of the

salivary glands. Such arrest is undoubtedly the result of primary influence exerted upon the chemical movements of protoplasm, either directly in the gland itself or through the nervous tissue which dominates the gland, and would therefore be said to be preceded by a chemical action or influence. On the other hand, the term physiological action might be used to express the primary impression produced by the drug upon the living tissue. Employed in this way, physiological action would itself be a chemical influence. We think the term is commonly employed by writers to indicate the results of the chemical influence rather than the primary influence exerted by the drug.—Eds.]

Notes and Queries.

FATAL RESULT OF PEROXIDE OF HYDROGEN INJECTIONS.

A Norwegian surgeon, DR. LAACHE, has reported a case in which a fatal result followed an injection of peroxide of hydrogen into the pleural cavity. The patient was a man 28 years of age, who had had a portion of the ninth and tenth ribs resected for empyema. The operation had been successful, and the wound progressed favorably, and two months after the operation there remained only a fistula about an inch and a half long. In order to hasten the healing of this, hypodermic injections of a three per cent. solution of peroxide of hydrogen were resorted to, as this method of treatment had given very satisfactory results in two somewhat similar cases in which it had been tried. Six injections, each containing 0.8 cubic centimetre of the solution, were administered without any particular effect. At the seventh, however, the patient complained of pain and faintness, the pulse failed, the respiration became oppressed, clonic contractions occurred in the right arm, the head turned to the left, the jaws became tightly set, the face became cyanotic, and the patient died in ten minutes. The necropsy, which was not made till forty-eight hours after death, revealed nothing very striking. The heart was dilated and contained liquid blood without air-bubbles; some ecchymoses were found in the parts of the left lung which were adherent to the chest-walls. In the fourth ventricle of the brain an ecchymosis the size of a pin's head was seen. A number of air-bubbles were present in the blood of the hepatic veins, and some were seen on cutting into

the spleen and kidneys. The cause of death was therefore by no means clear. Dr. Laache suggested that it may have been the small extravasation in the fourth ventricle or shock. Dr. Wulfsberg, who took part in the discussion on the case at the Christiania Medical Society, thought it was probably due to the introduction of the drug into the circulation. He thought that the strength of the blood-current might have carried the peroxide, if introduced into a vein, through the right heart and lungs almost unchanged, but that afterwards more oxygen might have been disengaged than the blood could absorb, and bubbles were thus produced, which may have been the immediate cause of death. Where animals have been subjected to injections of air into the veins, bubbles are not always found in the blood. In these cases Dr. Wulfsberg thinks that death has been due to paralysis of the heart, for when examinations have been made immediately after death bubbles have been found in the coronary arteries. As so long a time had elapsed before the necropsy in Dr. Laache's case, these might have been absorbed.—*Lancet*, October 9, 1886.

PILLS AND SYRUP OF SPARTEINE.

HOUDÉ recommends the following preparations :

1. Sulphate of sparteine, gr. viiss;
Excipient q.s. to make 50 pills.
From 2 to 10 pills daily.

2. Sulphate of sparteine, gr. v;
Syrup of orange, f3x.

One-half ounce of syrup contains $\frac{1}{8}$ gr. of the drug.

Germain-Sée and Laborde have shown that in doses of $1\frac{1}{2}$ grs. sparteine is valuable as a heart-stimulant, indicated both when organic lesions exist and when an impeded circulation taxes the heart. Its effect upon the pulse is prompt and marked, and its use has been free from unpleasant after-effects.—*Le Monde Pharmaceutique*, November 3, 1886.

EULYLYPTOL.

"Eulylyptol" is the name given by Dr. SCHMELTS to a mixture consisting of six parts of salicylic acid to one each of carbolic acid and oil of eucalyptus, which he considers preferable as an antiseptic to iodoform, corrosive sublimate, or carbolic acid. Dr. Schmelts considers that a chemical combination takes

place between the ingredients, since carbolic acid cannot be detected in the mixture. It is described as having a strong aromatic odor and an acrid burning taste, and as being nearly insoluble in water, but very soluble in absolute alcohol, ether, chloroform, and a mixture of equal parts of alcohol and glycerin. It is also soluble in ammonia and alkaline solutions. According to Dr. Schmelts, it completely arrests the fermentation of all putrescible substances, a small quantity added to urine, under any condition, being sufficient to preserve it during a month.—*Pharmaceutical Journal and Transactions*, October 30, 1886.

INFANT FEEDING.

There is the greatest divergence of opinion among practical and enlightened members of our profession on this most vital subject. The poor mother, unable to suckle her infant, has not alone to face the conflicting instructions of doctor and nurse, the first clinging tenaciously to his physiological doctrines in spite of the screams of the infant and its non-increase in weight, and the second maintaining the excellence of her patent foods and of her various "thickenings," regardless of the future rickets in store for the luckless child. But when doctors disagree, and especially doctors who speak with the authority of experience, the mother's bewilderment may well be great, and she is either tempted to fall back on the time-honored rule of thumb, or take refuge in the hypothesis of compromise that the proper course lies sometimes with one, sometimes with the other, and sometimes between the two. We shall not presume to adjudicate between the diverging views of our correspondents. With the limited knowledge at present available on the subject, they seem to us alike too sweeping and dogmatic for universal acceptance. Let us attempt the humbler task of indicating some simple homely tests which ought to be applied in any given case before we conclude that the method which has been adopted in that case is a satisfactory one.

The first test depends on the quiet and comfort of the child and the increase in body-weight. This increase ought to be from three to four ounces weekly, or more. The weight test is, however, by no means conclusive if taken alone. Many a hand-fed child when twelve months old is fat and plump, but is found to be rickety to an extreme degree; and it is well known to experienced nurses that breast-fed healthy in-

infants are often much less stout than those which are reared by hand. The advocate of any given method will not therefore settle the matter by simple weighings, although these count for a great deal.

The second test depends on the examination of the fæces. With regard to the frequency, there is a common belief that four to six is the proper number of daily evacuations for an infant during the early months of its existence. We hold this to be a mistake. Healthy breast-fed infants often pass not more than two stools a day after the first fortnight, and satisfactory hand-feeding ought to aim at a similar result. We hold that there is a presumption that an infant who passes regularly from four to six stools daily is passing a great deal of undigested food, and that so far the alimentation is imperfect. The wholesome fæces of a healthy breast-fed infant are of a bright gamboge-yellow, they are not unduly offensive, and they present very scanty traces of undigested casein. Now, in the majority of infants brought up on cow's milk, even diluted to the starvation-point, the stools are distinctly offensive, and are largely made up of masses of white casein. When this occurs, to find fault with the liver and do nothing more than prescribe the inevitable gray powder appears to us the most absolute empiricism, and the antiseptic cleansing of feeding-bottles and the banishment of tubes, excellent as these measures undoubtedly are, will not solve the difficulty in question.

How can the casein be dealt with? There are several methods open to us. First, it may be predigested wholly or in part. The simplest and readiest way of accomplishing this has, in our experience, been brought about by the use of one of the preparations suggested by SIR WILLIAM ROBERTS, which, made with fresh milk, is practically a partly-digested milk-gruel. But it is doubtful whether this method, invaluable as we believe it to be in selected cases, ought to be tried as the first routine step in dealing with the difficulty in question.

Sir William Roberts, in his lectures at the College of Physicians, referred to an observation of his own made while feeding a healthy kitten exclusively on predigested food. Without obvious or marked departure from health, the kitten, nevertheless, in respect of body-weight fell behind another kitten fed on milk. It was suggested that some atrophy of unemployed glands might be responsible indirectly for this failure in nutrition. Now,

in our problem, if we can get the infantile alimentary tract to digest for itself the casein masses, more will be gained than if the casein be predigested.

A simple, time-honored method, which we think ought always to be tried, is the dilution of the milk in varying proportions with barley-water, which, perhaps, in a mechanical way, facilitates the separation of the curd into more manageable masses. If this is found unsatisfactory, a very little malted food ought, we think, to be added to each bottle. That the whole character of the stools in respect of undigested casein may become altered after the adoption of this simple expedient we have satisfied ourselves again and again, as well as of the diminution in the actual number of the evacuations. But our physiological friends protest that this is using farinaceous food, that the infant's pancreas and salivary glands are rudimentary, and that its economy is unequal to the conversion of starch. To this objection there are several answers to be made. First, physiologically, it is by no means proved that the sole agents in the conversion of starch are the pancreas and the salivary glands, and experiments to prove the absolute incapacity of the infantile alimentary tract to convert a small amount of starch are not forthcoming. Again, in a good malted food, a great part of the starch has been already converted and rendered soluble. But let it be granted that, even after boiling, there is a small amount of unaltered starch; if the net result is that the fæces of the child are more wholesome and less frequent, that it does not suffer from vomiting, acidity, and flatulence, and that it is gaining weight, what evidence is there that the small amount of starch has done harm?

The employment of the term "farinaceous" has, indeed, brought us more or less under bondage in our directions as to infant feeding. To repeated meals of arrow-root, corn-flour, baked flour, and the like, even when made with milk, the term farinaceous is properly applicable, and we are second to none in our condemnation of such methods of feeding infants; but a broad distinction ought to be drawn between them, and the use of a very small quantity of malted soluble food added to milk. If even the malted foods be used in large relative proportion in early infancy, to the exclusion or great diminution of the quantity of fresh milk, we believe that serious risk is incurred in the direction of scurvy; and this is the more insidious because, with regard to the two tests which we have men-

tioned, the body-weight may certainly increase, and the stools may be less offensive and less frequent than under a milk regimen. The proper use of the malted foods is that they should be employed in small quantity, not in any sense as a substitute for fresh milk, but as an aid to the digestion of the casein.

We have said nothing about the humanized milk and the cream and whey methods. Useful as these plans have unquestionably proved hitherto, they have been methods for the rich and not for the poor, and their discussion may be for the present deferred.—*Lancet*, November 20, 1886.

AN INTESTINAL ANTISEPTIC.

BOUCHARD, in the *Revue Internationale des Sciences Médicales*, gives the following :

R Naphthaline,
Sacch. pulv., aa ʒiiss;
Ol. bergamot., gtt. iii. M.
Ft. pil. xxx.
Sig.—One every hour.

COMPOUND LIQUORICE POWDER.

DR. MARTIN OXLEY (*Lancet*) has ordered the following formula for some time past, in which anise fruit is substituted instead of the fennel, and one-fourth part of ginger is added. The altered formula runs thus: Senna and liquorice-root, of each 2 parts; anise fruit and sulphur, of each 1 part; sugar, $5\frac{3}{4}$ parts; ginger, $\frac{1}{4}$ part. This altered preparation is quite as satisfactory in its laxative properties, is less liable to gripe, and is as pleasant to take as the official powder, and he would suggest its trial in cases where the powder as now prepared produces the disagreeable effects to which he has referred.—*Boston Med. and Surg. Journ.*

TREATMENT OF GOITRE.

The injection of goitre with 5 drops of Fowler's solution twice weekly, and the daily exhibition of 5 drops of the arsenical solution and 12 grains of potassium iodide internally, is the treatment recommended by EICHBERG in *Les Nouveaux Remèdes*, November 24, 1886.

THE CAUSE OF CIRCULAR GASTRIC ULCER.

DR. SILBERMANN, of Breslau, has lately made some experiments on dogs for the pur-

pose of showing that the kind of anæmia characterized by deficiency of hæmoglobin in the red corpuscles of the blood is peculiarly favorable to the production and maintenance of circular ulcers of the stomach. Hæmoglobinæmia was produced by injection of various substances, and then either chromate of lead was introduced into a small gastric artery, or a ligature was applied to it, or the internal surface of the stomach was abraded by means of an œsophageal sound carrying a guarded point. All these animals were found to have contracted gastric ulcers, and it appeared to make no difference whether the hæmoglobinæmia was produced before or after the stomach was injured. With the microscope it was found that a number of the red corpuscles were of a very pale color, and that the blood was less alkaline than normal, which is explained by the experiments of Preyer, A. Schmidt, and Rollet, who have shown that hæmoglobin is a weak acid. Dr. Silbermann considers that in the anæmia of hæmoglobinæmia all the conditions are present which are required by various theories for the production of gastric ulcer,—namely, arterial anæmia (Klebs), venous hyperæmia of the gastric mucosa (Key), venous stasis in the hepatic vessels (Gunsberg), circumscribed hemorrhages (Virchow), and, lastly, diminished alkalinity of the blood (Leube).—*Lancet*, October 23, 1886.

TREATMENT OF ECZEMA IN CHILDREN.

Eczema in children is very successfully treated by WIDERHOFER with a five per cent. lanolin and bismuth salve. This is thickly spread upon linen, and bandaged upon the part morning and night. Lanolin forms but a small amount of fatty acids upon the skin, while vaseline and other fats readily produce fatty acids, which to the child's sensitive skin are very irritating.—*Allg. Wiener Med. Ztg.*, No. 32, 1886.

MYTILOTOXINE.

Numerous attempts have been made to effect the isolation of the poisonous principle in mussels. M. Salkowski has extracted by means of alcohol some harmful products, at present undetermined. The action of these products, however, recalls slightly the action of curare. M. BRIEGER (*Deutsche Med. Wochens.*) has succeeded in isolating this harmful principle, which he calls mytilotoxine, and at the same time several other bases, some

being harmless, while others are poisonous. These bases are precipitated after extraction with acidulated water or with alcohol by phosphomolybdic acid, perchloride of platinum, etc. One of the inoffensive bases appears to belong to the choline series; another, injected under the skin of small mammalia, produced salivation and profuse diarrhoea. Mytilotoxine is the most important of these bases: its composition ($C_8H_{10}NO_3$) M. Brieger has been able to determine possesses certainly the properties of curare, already recognized by Schmidtman, Virchow, and Salkowski. A fourth basic product is precipitated by gold perchloride in the form of an oil. It is very poisonous. Animals poisoned by it remain as though rooted to the ground, and succumb after a few convulsive movements. Lastly, M. Brieger points out a body with a detestable smell, recalling that of cacodyl. The greater part of these compounds appear to belong to the class of the ptomaines, and this specific principle disappears on distillation with carbonate of sodium, a fact announced by Salkowski. From this observation the following practical result arises: that decoctions of mussels may be rendered inactive by the addition of a little carbonate of sodium (three grammes to three and one-half grammes per litre of water), but the alkaline salt must be added while the mussel solution is boiling; in the cold solution it is inert, and is not, therefore, a true antidote. The action upon the muscles themselves is identical; boiling carbonate of sodium renders them harmless, at least to a certain extent.—*Druggists' Circular*, November, 1886.

A CURE FOR WARTS.

Take 15 grains of corrosive sublimate and dissolve in 1 ounce of collodion. Brush the warts carefully once a day with this solution. This remedy is more efficacious and more convenient than other recommended procedures.—*Zeitschrift d. Oester. Apotheker-V.*, September 20, 1886.

BINOXIDE OF MANGANESE IN AMENORRHOEA.

The effects of manganese in stimulating the menstrual flow, when its suspension is not due to pregnancy, have been fairly established by trials extending over nearly eighteen months. In the articles contributed to the medical journals on the subject, at the beginning of last year, the permanganate and the binoxide

were both mentioned as possessing emmenagogue properties; but experiments have so far been made almost exclusively with the permanganate. In consequence, however, of certain disadvantages which are apt to attend the administration of this salt, unless several conditions are complied with, aided, perhaps, by theoretical notions as to the transformation which so unstable a body may undergo immediately after being swallowed, the binoxide, which is equally potent and less irritating, has latterly come into favor. Manganic dioxide, it is true, has been described as possessing no therapeutical value; but it is conceivable that if its effects are limited, even approximately, to the menstrual function, they may have escaped the attention of observers, especially if, as is not improbable, their investigations were confined to men or animals.—*Brit. Med. Journ.*, December 4, 1886.

HOW TO PRESCRIBE HYOSCINE.

CLAUSSEN, in the *Zeitschrift für Therapie*, September 1, 1886, recommends the following formulas for the hypodermic and internal employment of hyoscine in asthma, whooping-cough, neuralgia, epilepsy, and paralysis agitans:

- R Hyoscini hydrobromici s. hydroiodici, gr. $\frac{1}{4}$;
Solve in aqua destillata, fʒiiss.
S.— $\frac{1}{4}$ to 1 syringeful for subcutaneous injection.
- R Hyoscini hydrobrom. s. hydroiod., gr. $\frac{1}{4}$ to $\frac{1}{2}$;
Aq. dest., fʒiiss;
Syr. cort. aurant., fʒi. M.
S.—Take a teaspoonful once or twice a day.

TAPIOCA-ROOT AS AN ANTISEPTIC.

A remarkable substance, which is possessed of powerful antiseptic properties, has been extracted by Dr. Peckolt from the roots of the tapioca-plant. To this the name of sepsicolytin, or fermentation-hinderer, has been given. A very small quantity, mixed with fresh albumen, is said to preserve it for upward of six months without deterioration. As this principle is in all probability present to a considerable extent in the well-known "cassareep" of the West Indies, it is obviously not poisonous. The possibilities of use for an antiseptic free from injurious action on the system are very great, both from a culinary and medical point of view. Its action on putrid fevers, and in all diseases in which albuminous changes take place rapidly, seems worthy of investigation.—*Provincial Medical Journal*, November 1, 1886.

CLINICAL LECTURE ON PAINLESS ENLARGEMENTS OF THE LIVER IN CHILDHOOD.*

BY LOUIS STARR, M.D.

GENTLEMEN:—Murchison, in his work on hepatic diseases, very aptly divides the affections of the liver attended by an increase in size into two classes,—the painless and the painful. It is my intention in this lecture to call your attention to the first class,

* Reported by Dr. Wm. J. Taylor, Physician to Children's Dispensary, Hospital of the University of Pennsylvania.

which is the more common in children, and which embraces amyloid degeneration and fatty infiltration of the liver. First let us study:

1. *Fatty Infiltration of the Liver.*—"Fatty liver" is a condition in which the enlargement is due to an accumulation of oil in the hepatic cells. A liver so diseased is increased in all its dimensions, its surface is yellowish and oily, its margins rounded, and its texture doughy. On section, the cut surface is distinctly yellow, mottled with brownish-red spots, and, if a bit be put under the microscope, abundant granules and globules of fat can be seen.

The little negro boy before you is about 3 years old, and has been a patient in the Children's Hospital for the past three months.

During this time he has suffered with severe cough; has had a temperature which, as you see by the chart, has oscillated markedly, ranging from 99° or 100° F. in the morning to 104° or 105° F. in the evening, and has lost strength and flesh rapidly. No previous history of value can be obtained, for his mother, who is a prostitute, left him to the tender mercies of chance friends, and knows little or nothing about him. He comes before you now, presenting a miserable spectacle. His face is pinched, and shows the imprint of severe illness. The lips are cracked and ulcerated, marking great impairment of nutrition, a fact still further manifested by the wasted thorax and limbs. From the latter all the flesh seems to have disappeared, and the investing skin hangs about the bones in loose inelastic folds. The abdomen alone appears to be unaffected by the general wasting, and by its prominence stands in marked contrast to the emaciated frame.

The general symptoms may be stated in a few words. They are fever, profuse night perspirations, harassing cough, accelerated breathing, rapid and feeble pulse, impaired appetite, thirst, and irregular bowels. There is no oedema, the conjunctivæ are pearly-white, and the urine is unaltered in composition.

To begin the physical examination with the lungs, as the cough and quickened respiration point to them as the seat of the disease, you perceive that there is greatly impaired resonance on percussion over the upper third of the right lung, and auscultation reveals the signs of a small cavity immediately below the clavicle, with broncho-vesicular respiration, and subcrepitant râles over the rest of the dull area. Over the remainder of the right and the whole of the left lung there is hyper-resonance on percussion, and exaggerated puerile breathing on auscultation. The heart, beyond rapidity of action, presents nothing abnormal.

Passing next to the abdomen, note that while the whole region projects markedly, the greatest bulging is at the upper half. In this position the fingers of the palpating hand distinctly detect a solid, smooth mass beneath the integument, which extends upwards to the costal border and downwards to the level of the umbilicus. The lower border is somewhat hard to find, as it seems to fall away from the parietes, but on careful manipulation it can be grasped by the fingers, and is rounded and soft. On tracing this from right to left, one can distinctly mark out an outline exactly

resembling that of the right lobe of the liver; while here, a little to the left of the meridian line, is the notch between the right and left lobe, and still more to the left, the margin of the left lobe. To further prove that this mass is an enlarged liver, the dulness over it is continuous with the usual liver dulness, and the upper margin of the latter extends nearly an inch higher than in health. The abdomen below the tumor gives the ordinary tympanitic note on percussion, and is soft and flexible to palpation. There is no enlargement of the spleen. It is particularly to be observed that during the whole of the abdominal exploration the child has evinced no signs of pain nor tenderness. Now, all of these features are characteristic of fatty infiltration of the liver.

The case before you, therefore, is one of tuberculosis with associated fatty liver.

The pulmonary disease undoubtedly antedated and induced the hepatic enlargement, and I think you will be able to trace this etiological factor in the majority of cases occurring among children. The causes, however, may be divided into two classes,—first, the over-use of farinaceous food, which induces a physiological and transitory infiltration of the liver, the excess of hydrocarbons supplied from without being deposited in the cells in the form of fat; second, chronic wasting diseases, such as *tubercle*, *scrofula*, rickets, caries of bone, chronic intestinal catarrh, and syphilis. Here the fat is absorbed from the subcutaneous and other fat-forming tissues of the body, and the process is pathological.

The rational symptoms, as exemplified in the present instance, belong usually to the causal affection rather than to the hepatic disease. In fact, the latter has no especial symptoms, except disturbance of the functions of the stomach and intestines due to obstruction of the portal circulation; the features of associated fatty changes in the heart and kidneys, that so often direct attention to, or confirm the existence of, similar lesions of the liver in adult life, being of rare occurrence in childhood. Symptoms, therefore, are little to be relied on.

The physical signs so readily elicited today are, on the contrary, quite characteristic. Unfortunately, they are fully developed only in well-matured cases. For, while uncomplicated fatty infiltration of the liver is always attended by an increase in bulk, we may fail to detect a moderate alteration on account of the tendency the organ has, from its softness, to fall away from the abdominal wall.

Understand, then, that the presence of this disease may be absolutely asserted when a tumor, having the outline of the liver, can be felt in the abdomen; when this tumor has a blunted edge, is soft and painless; when the percussion-dulness over it is continuous with the normal liver-dulness; and when there is neither enlargement of the spleen, ascites, nor jaundice. Without these features there must always be uncertainty, and sometimes the lesion is not even suspected until the viscus is exposed on the post-mortem table.

The diagnosis between fatty and amyloid liver is best tabulated as follows:

FATTY LIVER.	AMYLOID LIVER.
Increase in size; the lower margin of right lobe rarely extending lower than the level of the umbilicus.	Increase in size; the lower margin of right lobe often extending down to brim of the pelvis.
Tumor soft, smooth, and doughy.	Tumor smooth but very hard.
Edge blunted, and receding from abdominal wall.	Edge sharp and prominent, often pushing forward the parietes in a visible ridge.
No pain nor tenderness.	No pain nor tenderness.
Spleen normal in size.	Spleen enlarged and hardened.
Impaired gastro-intestinal digestion.	Vomiting and diarrhoea from amyloid degeneration of the mucous membrane of the gastro-intestinal tract.
Urine usually normal.	Urine albuminous, with hyaline tube-casts from amyloid degeneration of the kidneys.
Anæmia.	Anæmia and sometimes œdema of feet and ankles.
No ascites.	No ascites.
No jaundice.	No jaundice.
Usual cause: tuberculousis.	Usual cause: protracted suppuration.

In very exceptional cases, jaundice and ascites are met with in both forms of disease. They depend upon enlargement of the glands in the fissure of the liver, due in the one case to caseous or tubercular, and in the other, to amyloid degeneration.

The prognosis depends upon the cause. If the enlargement be caused by an excess of farinaceous food, regulation of the diet soon produces a reduction in bulk, but when it occurs during the course of a protracted wasting disease, dangerous impairment of nutrition is indicated.

As already stated, then, when fatty liver depends upon dietetic causes, proper feeding is all that is required for its removal. In other cases, the only successful treatment is one directed against the originating disease. So

far as the liver itself is concerned, the plan of management is to exclude all starch and fat from the food; to insist on warm clothing, fresh air, and sunlight; to correct dyspeptic symptoms by the administration of alkalies with bitters; to relieve constipation by mild laxatives; and to restore the crasis of the blood in anæmia by the use of some acceptable preparation of iron.

2. *Amyloid Degeneration of the Liver.*—The little patient before you is 8 years of age. He has been an inmate of the Children's Hospital for over three years, and during this time has been treated for suppurative disease of the right hip-joint. He is very anæmic and much emaciated, suffers from attacks of vomiting and diarrhoea, has slight œdema of the ankles and feet, and his urine is highly albuminous and contains numerous hyaline casts. The abdomen is, as you see, very prominent, and on physical examination the liver is found to be immensely enlarged, the lower edge of the right lobe extending quite to the brim of the pelvis; the spleen is also greatly increased in size, and both organs feel firm and dense to the palpating fingers. There is no jaundice nor ascites, and no pain nor tenderness over the liver. There can be no question that this is a case of amyloid degeneration of the liver, with associated amyloid disease of the spleen, kidneys, and gastro-intestinal mucous membrane.

The albuminoid or amyloid liver occurs as a factor in general amyloid degeneration, and is not infrequently met with in childhood. The disease consists in a complete or partial infiltration of the liver-cells by a peculiar translucent, refracting substance, possessing the property of fixing iodine, and assuming a mahogany-brown color, which, upon the application of sulphuric acid, changes to blue, green, violet, or red. This infiltration begins in the hepatic arterioles and capillaries, and at first is limited to the middle zone of the lobules; it then extends to the periphery and centre, destroying the normal elements of the cells, and converting them into irregularly-shaped, glassy-looking masses; with this condition fatty infiltration is sometimes associated.

There is uniform enlargement of the liver; its density is increased; the color is yellowish-gray; the peritoneum is smooth and shining, and the edges are thin and well defined. On section, dry, homogeneous, glistening surfaces are exposed.

The spleen, kidneys, and lymphatic glands are frequently similarly altered, and at times,

also, the mucous membrane of the stomach and intestines.

Amyloid degeneration of the liver is always produced by some chronic disease, attended by suppuration and purulent discharge. Suppurative diseases of the bones and joints, scrofulous abscesses, empyema with a fistulous opening in the chest-wall, dilated bronchi with copious muco-purulent expectoration, chronic pulmonary tuberculosis, and constitutional syphilis are the most frequent causes. It may occur at any age, but is more frequent after the fifth year, and in boys than girls.

The rational symptoms are those of the originating disease. There is no pain nor tenderness in the hepatic region; there is absence of jaundice, distention of the superficial abdominal veins, and ascites. If, however, the glands in the fissure of the liver be at the same time enlarged by waxy deposit, the pressure exerted upon the portal vein and bile-duct will cause jaundice, distention of the superficial abdominal veins, and ascites. The patient may complain of weight in the hypochondrium, and is always weak, wasted, and anæmic, with pale, sallow skin, clubbed fingers, and œdematous feet and ankles. If the kidneys be involved, the urine is increased in quantity, has a low specific gravity (about 1014), is light lemon-colored, and contains albumen, and at times hyaline tubercasts. The dropsy of the lower extremities is due in great measure to this complication, and when the intestinal tract becomes involved there is a tendency to vomiting and diarrhoea.

The physical signs are characteristic: the abdomen is prominent, especially over the upper third, and both percussion and palpation show the liver to be very greatly and uniformly enlarged.

The upper margin of dulness is higher by an inch or more than is normal, while the lower edge of the right lobe is somewhat blunted, but perfectly well defined, and can often be felt below the level of the umbilicus, even, as in the present case, at the brim of the pelvis. The portion uncovered by the ribs feels very dense and firm, and perfectly smooth, except where broken by the natural fissures.

The spleen can often be detected projecting from beneath the left costal border. The absence of splenic enlargement is, however, no proof against the existence of amyloid changes in that organ, as in some few cases there is no appreciable alteration in size.

The course of the disease is chronic.

The diagnosis is not difficult, and is readily made from the physical signs furnished by the liver and spleen, the absence of jaundice and ascites, the previous history of cachexia and suppuration, the character of the urine, the anæmia, and the gastro-intestinal symptoms.

Congestion of the liver, with consequent enlargement, has an entirely different history, rarely occurring in cachectic or anæmic cases. A fatty liver, while large, is soft and yielding to the touch, and is unattended by increase in the size of the spleen or albuminuria.

The prospect of ultimate recovery is better in children than in adults, for, provided the cause of the degeneration can be removed, it is quite possible for the liver to return to its normal dimensions and to an apparently healthy condition, through the active reparative power always present in early life. Nevertheless, amyloid change in the liver adds greatly to the danger of the originating disease, and is fatal in most cases.

In the matter of treatment it is hardly necessary for me to say that attention must first be given to the amelioration or removal of the cause. It is more difficult to cure the disease when once developed than to prevent it by checking chronic suppuration, removing carious bone, healing diseased joints, energetically treating constitutional syphilis, and building up the health in cachectic subjects.

To combat the disease itself, the diet must be as nutritious as possible, taking care that the powers of digestion be not overtaxed, and a moderate quantity of alcoholic stimulants must be taken daily. The child must be clothed so as to prevent all chilling, and must live as much as possible in the sunlight and open air, or, if confined to the house, in a bright, airy room. Alkalies, iron, and iodine are the most useful drugs. Of alkalies, the chloride of ammonium is the best, and it may be given in combination with a bitter. The following prescription answers very well in these cases:

R Ammonii chloridi, ʒii;
Infus. gentianæ comp., fʒiii. M.

S.—One teaspoonful four times daily; for a child six years old.

It is often well to combine iron with the ammonium salt; for example:

R Tinc. ferri chloridi, fʒi;
Ammonii chloridi, ʒii;
Infus. calumbæ, q.s. ad fʒiii. M.

S.—One teaspoonful three times daily.

The iron may also be given in the form of a modified Basham's mixture :

R Tinc. ferri chloridi, ℥i;
Acidi acetici dil., ℥iiss;
Liq. ammonii acetatis, ℥x;
Elix. aurantii, ℥v;
Syrupi, ℥i;
Aquæ, q.s. ad ℥vi. M.

S.—One tablespoonful four times a day.

When there is kidney complication with œdema, this formula is particularly useful.

Iodine is most efficient if there be a syphilitic taint. It may be given in the form of iodide of potassium, 5 grains or more three times a day, with a bitter infusion, or liquor iodinii comp. can be employed in doses of 2 drops, well diluted, three times a day.

The complications must be met as they arise. Vomiting, by ice, Apollinaris water, bismuth, and counter-irritation of the epigastrium; diarrhœa, by the vegetable astringents, combined with small doses of opium; and dropsy, by diaphoretics and diuretics.

DIET IN FEBRILE MALADIES.*

BY PROFESSOR DUJARDIN-BEAUMETZ, Paris, France.

GENTLEMEN:—If I were to attempt to give a full history of the subject of which I am to speak to-day, one lecture would hardly suffice for all the details, or even to indicate the various phases through which this vexed question of hygienic therapeutics has passed. I shall, then, call your attention only to the principal points of historical interest connected with the dietetics of fevers.

For long ages the medical world followed scrupulously the rules pertaining to diet in febrile diseases so remarkably set forth by the Father of Medicine. In the treatise which he has devoted to this subject, Hippocrates expresses himself thus: "Doubtless in cases where there is much enfeeblement, resulting from pain and acuteness of the malady, it is a great mistake to give the patient large quantities of drinks, ptisans, or alimentary substances, with the idea that the debility is due to the emptiness of the vessels, but it is a mistake, also, to lose sight of the fact that a fever patient is weak by inanition, and to make his state worse by starving him." He adds, with much good sense and discernment, "If, under such circumstances (where the patient has been subjected to a starvation diet), some friend or

neighbor, wholly unacquainted with medicine, comes in and recommends nourishing food and drinks, despite the doctor's orders, he will often greatly benefit the patient, and may even get the credit of a cure. It is such cases as these that bring reproach upon the physician, the new man who prescribes food, whether a physician or a layman, receiving praise for having wrought an astonishing cure."[†]

Galen, Celsus, Ætius, Paulus of Ægina, followed rigidly, with comments of their own, the precepts of Hippocrates, which were summed up in these words: "When you have an acute inflammatory or febrile disease to deal with, you must treat it by a rigorously low diet." At the same time complete abstinence was not enforced, for physicians of Hippocrates's school were in the habit of administering in the acute stages of disease a plentiful supply of infusion of ground barley, which has given to ptisans their generic name (*πτισανή*, ground barley). The medical men of antiquity rarely broke through these traditional rules. One of the most curious of these infractions is that of Petronius, who allowed febricitants meat, for which Galen bitterly reproached him.

But towards the end of the eighteenth century (in 1780), when Brown gave to the world his "*Elementa Medicinæ*," which was destined to revolutionize medical practice, the doctrine of Hippocrates relative to the dietetic treatment of fevers underwent modification. Regarding almost all acute febrile diseases as asthenic affections, the Scotch reformer counselled in their treatment a stimulant and tonic regimen in which food played an important part. These views found a fitting soil in England; they were welcomed also in Scotland, and long afterwards we find Graves successfully defending Brown's doctrine, and showing the danger of abstinence in fevers. He, in fact, considered this position which he had taken respecting diet in fevers as such an important factor of his medical career that he is said to have desired to have this inscription on his tombstone: "*GRAVES FED FEVERS*."

In France for many years the doctrine of Brown found few partisans; Broussais's physiological system was in fashion, and opposed an invincible barrier to it. Considering all febrile diseases as dependent on gastro-intestinal irritation, the ardent reformer of Val de Grâce, more severe than Hippocrates, condemned his fever patients to absolute ab-

* A lecture on Alimentary Therapeutics.

† Hippocrates, "On Regimen in Acute Diseases."

stinence. Ignorant of the fact that at the terminal periods of continued fevers the nourishment which these patients at that time require provokes a physiological fever (*febris carnis*), as Bordeau had before observed, Broussais would rigorously remand to low diet or entire abstinence the poor patients who experienced the least febrile return as a result of the first ingestion of food, and it may now be affirmed, without fear of contradiction, that this practice, as judged by its fruits, was most disastrous.

When, at length, the medical profession in France had advanced sufficiently to throw off the yoke imposed by the school of Broussais, more rational views as to the dietetic treatment of fevers began to prevail; the starvation regimen of Broussais was repudiated, and, despite the earnest endeavors of Forget, who took a vehement stand against these "fever-feeders," as he called them, and who naïvely wrote that there was something better to do than to *feed* fevers,—namely, to *cure* them, the great majority of physicians recognized the dangers of abstinence in febrile maladies; the bed-sores so often witnessed in typhoid patients, with other untoward incidents, were laid to the charge of poverty of alimentation,—*i.e.*, were attributed to the abstinence to which the patients had been subjected.

The contest was carried on with ardor by such men as Marotte, Trousseau, and Herard, and in a remarkable discussion which was held almost thirty years ago (in 1857), at the meeting of the Society of the Hospitals, all present were agreed in acknowledging the necessity of feeding persons suffering from febrile affections. If Trousseau, by the eloquence of his teaching, by the charm of his manner, and his personal magnetism, was the most popular advocate of this new mode of alimentation, it must be remembered that it was Monneret who the most boldly carried it out. He was in the habit of ordering broths, vinous lemonade, wine of quinine, and Bagnol's wine for his typhoid patients, and would make them take as much as six quarts a day of nutrient and stimulating drinks.

Note, also, that several years before the prize Corvisart was awarded to a work of Duriard on abstinence in acute diseases, the conclusion of which was as follows: "Abstinence has no influence on the progress of acute diseases; it neither modifies their march nor their manifestations." Thus far only clinical observation had been invoked in favor of or in opposition to a generous ali-

mentary regimen in febrile disorders; but latterly new means of investigation have been put in exercise, and we shall presently see what support these have furnished to either the one or the other of the conflicting views which the medical world has entertained.

To give method to my exposition, I shall first examine the modifications which the febrile process effects in the functional operations of the digestive tube, and in nutrition.

As far as the functions of the digestive tube are concerned, all observers are agreed that typhoid fever profoundly modifies the secretions of the alimentary canal. In experiments made on individuals, the subjects of a gastric fistula, it has been again and again remarked that one of the first symptoms of this fever was marked diminution of the secretion of gastric juice, and even a decided change in the composition of this fluid. It is the same with the other secretions of the digestive tube.

But the most important point is that when you examine the condition of the intestinal mucous membrane in certain fevers, as typhoid fever, the modifications in the functions of this mucosa are still more pronounced. In this disease, in fact, the entire net-work of lymphatics is affected; the mesenteric glands are inflamed, so that the functional operation of the lacteals is profoundly perturbed, and the absorption of emulsified fatty substances and of peptonized albuminoid aliments cannot be effected in the greater part of the small intestine and in the large intestine. Drinks only can penetrate the economy by the venous plexuses of the portal vein.

The question of nutrition is also one of prime importance. I cannot here enter into a general description of the phenomena which characterize fever. Suffice it to say that we know by the examination of the urine on the one hand, and that of the gases of respiration on the other, that the febrile hyperthermia results either from a more active disintegration of the organism, with diminution of the combustions, or from an exaggeration of the combustions. The first theory is held by those who take for their basis the cellular theory of nutrition, and who consider urea as a breaking up of albuminoid substances; the second is held by those who accept as true the views of Liebig, and who regard urea as the direct result of organic combustions.

We have, moreover, a direct proof when we examine the loss of weight of fever patients. In a very interesting thesis, unfortunately in-

complete, by Thomas Layton,* you will find precious indications concerning this loss of weight in different febrile processes. In typhoid fever the mean loss of weight is 238.672 grms. per day; in pneumonia it is 387.6 grms.; in acute articular rheumatism, 386.8 grms. These averages have only a relative value. What it is important to know is the march of this loss of weight in the course of a continued fever. This is what Thomas Layton has not shown very conclusively, and I must protest against one of his affirmations, that in acute febrile maladies the loss of weight is uniformly descending.

You know that from a clinical point of view this is not the case in typhoid fever, where we see the patient preserve, at least in appearance, his ordinary plumpness, to emaciate with extreme rapidity during the first days of his convalescence. The observations, far too few, made by Lorraine, with the help of the scales, do not permit us to decide this question definitely.

Therefore I propose to take up anew this question by instituting daily weighings of my typhoid fever patients, and by comparing the temperature, the urea-production, and the diminution of weight. This is a work of no little magnitude, which will require a long time, but which will enable me, I believe, positively to demonstrate that in typhoid fever the denutrition does not follow, as Monneret and Layton think, a uniformly descending course, and that, on the contrary, it is vastly more pronounced at the decline of the febrile process and in the first period of convalescence.

But this is only one aspect of the question. There is another which presents still greater interest,—namely, the ascertainment of what becomes of the products which result from the disintegration of the organism. This point has been particularly well studied recently by our colleague, Albert Robin. This clinical experimenter has shown us that these products of disintegration accumulate in the economy, and to such an extent that you will find, for instance, in the blood of typhoid patients as much as seven and even nine per cent. of extractive matters, while in the normal state the proportion does not exceed four or four and one-half per cent. The extractive matters are eliminated chiefly by the urine, but also by the fæces and perspiration;

and the mildness or gravity of the fever depends on the greater or less facility with which this elimination goes on. There are even at certain moments *periods of discharge*, during which the economy eliminates immense quantities of these extractive matters. These are the “crises” which we witness in the course of continued fevers.

But these extractive principles which thus accumulate in the blood, and which result from the disintegration of the organism, are not the only toxic principles which poison the economy in continued fevers. We are obliged to add the ptomaines and the leucomaines, which take their origin, on the one hand, from septic processes which go on in the digestive tube, and on the other from the presence there of micro-organisms or bacilli. Bouchard and Lépine have clearly shown by the examination of the urine of typhoid patients and its toxic effects the presence of these different products. Thus it is that Lépine has demonstrated that in the normal state the organic matters (products of disintegration) compose but fifteen per cent. of the total toxic ingredients of the urine, while in the febrile state the proportion is as high as forty-five per cent.

From all that goes before, it results, then, that in febrile processes, and in particular in typhoid fever, the digestive tube is not in a fit condition, on the one hand, for the absorption of albuminoid matters, and, on the other hand, the products of organic disintegration accumulate in the system and produce toxic phenomena.

What can be the rôle of alimentation in such cases? Dietetics have a very limited rôle, because only substances which are liquid and charged with salts can penetrate the economy, while albuminoids and fats find in the altered state of the lacteals a serious obstacle to their absorption. In the case which we have under supposition, of typhoid fever, the fatty and albuminoid principles will be furnished, not by the food ingested, but by the individual, who will consume his own fat and muscles.

Reduced to this simple question of the penetration of saline and aqueous matters, diet does not the less play a considerable part in the course of febrile maladies, on condition, however, that the food administered shall be of a liquid nature. The milk and broth which we give to typhoid patients allow us to introduce, on the one hand, a large quantity of water, and, on the other hand, salines in considerable amount. In typhoid

* Layton, “Clinical Study on the Influence of Causes which alter the Bodily Weight of the Adult Sick Person.” (*Thèse de Paris*, 1868.)

fever, as Albert Robin has well shown, there is a veritable *mineral inanition*, resulting from the daily losses in potassium, in sulphuric acid, in phosphoric acid, and in chloride of sodium,—losses which take place by the urine, and which amount to 3 or 4 gms. of chloride of sodium, 1.50 gms. to 2 gms. of phosphoric acid, 2.967 gms. of sulphuric acid, and 1.730 gms. of potassium. If you will now refer to the analysis of broth which I gave you in one of the first lectures, and which I here repeat, you will see how well this analysis corresponds to the incessant losses of typhoid patients in saline matters :

	Per 1000.
Water.....	985.600
Solid organic substance, desiccated at 20° C. in a dry vacuum.....	16.917
Soluble salts, chlorides, phosphates, and sul- phates of potassium and sodium.....	10.720
Salts slightly soluble, phosphates of magnesium and lime.....	0.539
	1031.780

Can the same be affirmed with regard to milk? Yes, to a certain extent. By the water and the saline substances which it contains, and which strikingly resemble those of serum, milk responds well to the indication for a liquid and saline nourishment in febrile maladies. But milk contains albuminoids and fats besides. What rôle do these ingredients play? Do they act as food, or are they rejected without being absorbed? We are entirely ignorant; and careful experiments, made with the scales, between typhoid patients fed exclusively with broth and such as have been fed exclusively with milk, will alone enable us to solve this question. For myself, I believe that milk does good in febrile maladies only by the water and saline substances which it contains.

If the saline principles which enter into the composition of foods are suitable for repairing the incessant saline losses of fever patients, the water which is a part of these same aliments answers quite another end,—namely, that of promoting elimination by the urine of the extractive matters accumulated in the economy. This end will be fulfilled not only by the aqueous foods, such as broth and milk, but also by the ptisans, at the head of which we must place lemonade, and this not only by reason of its agreeable taste, but also because quite special antifebrile properties have been attributed to the lemon.

The Arabian physicians, and in particular Isach-Ibn-Amrem, have since a remote period pointed out the advantageous action of lemon-

pulp in fevers; and Maglieri, who has lately made trials of this simple remedy in Italy, affirms that the decoction of lemon is equal, if not superior, to quinine. Without going as far as this, one may admit that lemonade fulfils a useful rôle in fevers by introducing water and certain saline principles. But there is a point which ought to arrest our attention a little longer. I refer to wine and the alcohols.

Wine and alcohol have been for ages utilized in the treatment of acute diseases, and in the works of Hippocrates we find frequent allusions to the employment of wine as a tonic and stimulant. But it must be remembered that it is only within the last twenty-six years—that is to say, since the publication of Robert Bentley Todd's classical work,—that alcohol has been methodically employed as a part of the routine treatment of inflammatory and febrile diseases. Todd, in the propositions which he lays down with reference to acute diseases, maintains that the duty of the physician is to find the best means for supporting the vital forces in acute diseases whose natural evolution is towards cure. According to Todd, there is no means for sustaining the vital forces so efficacious as alcohol.

My regretted master, Behier, was one of the most earnest advocates of Todd's method, and it was soon the fashion in France to treat all acute inflammations, such as pneumonia, by alcoholic stimulants. Jaccoud has given in this regard some statistics borrowed from Bennett, which are very favorable to this kind of treatment, out of one hundred and twenty cases of pneumonia the mortality being but about three per cent. In cases of treatment by pure expectancy, the mortality rose to 7.4 per cent., and this was strikingly contrasted with a death-rate of from sixteen to thirty-four per cent. in pneumonias treated by blood-letting and tartar emetic.

This same method has been applied to the therapy of fevers. Fourrier, of Compiègne, showed us in 1873 the good effects which he had derived from alcoholic stimulants in typhoid fever.* Burdel, moreover, has called our attention to the advantages of wine in malarial fevers, and curious instances have been mentioned of individuals affected with intermittent fever rebellious to all other means of treatment, who were cured by dosing them freely with alcohol. Todd had observed similar cases.

To-day, now that the enthusiasm which was

* Fourrier, *Bull. de Thér.*, t. 85, p. 241.

at first awakened by the publication of Todd's views and the results of his practice has subsided, there is, nevertheless, unanimity in recognizing the great advantages of the alcoholic medication in acute febrile maladies. It is more especially in the adynamic forms of these affections that the alcohols are indicated. They also give excellent results in the two extremes of life, infancy and old age. In infancy, as our colleague, Gingeot,* has well shown,* alcohol is remarkably well borne, and gives the best results in the treatment of pneumonia; this is also the case in old age. Add, lastly, that in the case of persons addicted to the free use of alcohol, when they are attacked by acute diseases, grave symptoms are almost sure to supervene if the usage of alcoholic stimulants is abruptly suppressed, and we see the necessity in such patients of maintaining the treatment instituted by Todd.

To sum up, then, it is in fevers of an adynamic kind, in the extreme periods of life, and in patients of intemperate habits, that we find the three great indications for the use of alcohol in febrile maladies.

If everybody is agreed in recognizing the good effects of the tonic medication in these diseases, this unanimity ceases when we endeavor to explain what is the mechanism of this favorable action. Some, as Gubler, see in alcohol only a dynamic or force-giving medicament, which acts in fevers by sustaining and augmenting the vital powers. Others consider alcohol as an antithermic medicine, which brings down the temperature and opposes hyperthermia. Still others maintain (and among them Albert Robin) that alcohol opposes organic disintegration, while augmenting the quantity of oxygen inhaled; others, lastly, affirm that alcohol acts only as a food.

For my part, I have deeply studied this question of the physiological action of alcohol, and I believe that all these views are to a certain extent true, and that alcohol acts at once as a food, as a tonic, and as an antithermic; and it is this threefold action which explains its utility in the treatment of acute febrile maladies. I believe alcohol to be a food, and claim that it undergoes a more or less complete combustion in the organism; but this combustion takes place at the expense of the oxygen of the blood. On this account alcohol retards the organic combustions and lowers the temperature; in fact, as Marveaud

has maintained, it is a waste-restraining aliment. But it acts also unchanged on the nerve-centres, to which it communicates elements of strength and tonicity, and is a force-producer, as Gubler regarded it.

In our hospital practice we are much in the habit of prescribing alcohol, under the form of Todd's potion, which consists of equal parts of rum or cognac and the *potio diacode*. (The *potio diacode* may be conveniently replaced by sweetened water.—TR.)

In private practice I think that it is better to discard Todd's potion, and the various modifications thereof, and to substitute certain wines rich in alcohol, such as the Spanish, Portuguese, or Sicilian. These wines are much more agreeable than Todd's mixture. It is desirable to obtain such wines in their purity, which is easier far than to obtain pure brandy, the brandies of commerce being generally an artificial rather than a natural product.

To sum up, gentlemen, diet in febrile maladies, and, in particular, in typhoid fever, ought to consist of liquid substances, containing, besides the water of their composition, certain saline ingredients, tonic principles, and a very small percentage of albuminoid principles.

But this regimen should be rigorously observed, especially in the terminal periods of typhoid fever, at the moment when, with the subsidence of the fever, the patient enters into convalescence.

To repair the losses which prolonged inanition has inflicted on the organism, the fever patient, during the first period of convalescence, is possessed of an insatiable appetite, which causes him to devour everything offered him with avidity. He bolts his food whole, always craving for more. The result is, that the digestive tube is soon encumbered with a load of alimentary substances, which, in its weakened state, it is unable to digest; what with the irritation of the food, and the flatus produced by its decomposition, rupture of the intestines, with fatal peritonitis, is very likely to follow. This rupture is easily explained, when you think of the imperfectly cicatrized ulcers which exist in the ileum. Here, then, your earnest watchfulness ought to be exercised in enforcing extreme moderation in eating, and in permitting only such articles of food as are readily digestible, and are in a state which allows their speedy absorption, the daily rations being little by little augmented as the patient advances towards recovery.

† Gingeot, "Treatment of Pneumonia of Children by Alcohol." (*Thèse de Paris*.)

Such, gentlemen, are the indications which I desired to present relative to diet in febrile maladies. I have done with this first part of hygienic therapeutics. I hope that this study of alimentary hygiene has proved of some interest, and that continually in your practice you will be enabled to apply the precepts which I have laid down. But only a part of my task is accomplished. In another series of lectures I shall complete this subject of hygienic therapeutics by taking up gymnastics, hydrotherapy, balneotherapy, aërotherapy, and climatotherapy, and we shall find under these different heads topics of great interest, and presenting a real utility.

CRITICAL OBSERVATIONS AND EXPERIMENTAL STUDIES ON THE INFLUENCE OF PHARMACOLOGICAL AGENTS ON PERIPHERAL VESSELS.

BY PROF. R. KOBERT.*

(Continued from page 14.)

PART II.

RANKE† makes the following assertion: The walls of all vessels excepting the capillaries contain nerves which form a fine net-work under the adventitia. Also ganglionic cells have been discovered in the larger nerve-nets. According to W. Wundt,‡ the arteries and veins contain, like the heart, ganglia in their own walls which act as centres of innervation. Besides, they also receive their nervous supply from outside, and consequently depend, as far as their condition is concerned, on both an outward and an inward influence. The smaller arteries, in particular, are subjected to this double source of innervation.

According to Aubert,§ the statements of observers vary materially as to the microscopic behavior of the vascular nerves. Ganglia seem to have been observed only by Beale|| and Lehmann,¶ and by the latter exclusively in the vena cava of the frog. Arnold** has described and drawn a nerve-plexus, with nuclei and terminal nodes, in the muscular

coat of a small artery. Henocque†† described several plexuses on the arterial walls. One of these, the basic plexus, lies at the outer side of the tunica externa; another plexus, the intermediary one, lies in the tunica externa, is derived from the former, and contains nuclei, nodules, and ganglionic swellings; and, finally, an intramuscular plexus, which is derived from the former in the form of very thin fibres, and terminates in the muscles.

Gonjaew,‡‡ however, and, following his example, Gscheidlen, §§ found in the arteries only one net situated in the adventitia, and another one, connected with this, and situated in the muscular coat. Ganglionic cells could not be found by Gscheidlen, though he saw in the vena cava of the frog structures suggestive of ganglionic cells. The terminal reticula of the vaso-motor nerves in the capillaries have been described by Gonjaew and confirmed by Ch. Legros.¶¶

Rouget, Goltz, and the majority of the more recent physiologists, explain the dilatation of vessels, whenever it is independent of the blood-pressure, by the presence of a peculiar mechanism in them, which is allied to the inhibitory apparatus of the heart. In other words, they claim that there exists in the walls of the vessels a *special peripheral ganglionic apparatus which maintains the vessels constantly at a certain level of tension*. The nerve-tracts connected with these ganglia either increase the activity of the former, and thus contract the vessels, or inhibit—i.e., decrease—their energy, and thus produce a dilatation of the vessels. According to B. v. Anrep and N. Cybulski, this latter hypothesis is in perfect accord with all the established facts of anatomy and physiology.

The above quotations indicate that though the anatomists have not quite settled the question of the existence of these peripheral vascular ganglia, their presence is required from the physiological point of view. Goltz, with whom, when his assistant, I had often spoken of this subject, has somewhat modified his former view, inasmuch as he no longer insists upon the necessity of anatomically visible ganglia. He believes, however, that the walls contain some independent regulatory apparatus endowed with the power to dilate and contract the vascular lumen. And this

view I also hold myself. It cannot, of course, concern us here whether this regulatory mechanism refers solely to the muscular coat, or whether the tunica elastica and adventitia also participate in it.

It has likewise been a matter of discussion which portions of the circulatory system are subject to this contraction and dilatation of the lumen. Thus Eckhard speaks of an active dilatation of the *capillaries*. Again, other experimenters who have instituted investigations with digitalis and ergot, speak of a contraction of capillaries terminating in absolute disappearance.

I have never been able to distinguish any appreciable variations in the lumen of capillaries. On the other hand, all observers agree that *arteries* can contract and dilate, and that these variations of the lumen are particularly distinct in the smaller arteries. In veins a contraction has also been noticed by a few observers. At the exhibition of certain agents, of which I shall speak below, I have invariably seen this contraction, and feel disposed to interpret this phenomenon as an active change.

Speaking of the calibre of vessels, I wish to mention still another appearance which manifested itself in every experiment. As soon as the canules were fastened and the transfusion began, all vessels at first became filled and turgid, and the organ assumed a highly sanguineous appearance. The vein also carried a copious stream, which was only from time to time interrupted by a larger coagulum, which had to be expelled. In this stage the organ had not yet attained complete vitality. As soon, however, as the temperature of the blood has been reached, a great contraction of all vessels is suddenly seen to set in, pallor takes the place of ruddiness, and the venous flow decreases considerably. This stage of active contraction has to pass off first before a regular flow and the beginning of measurement can be thought of.

As to the *quantity of the blood flowing off in a unit of time* (a minute), I found this to vary materially, according to the nature and the size of the organ. On isolated portions of a rabbit's uterus the quantity, of course, was very small, amounting frequently to less than 1 c.c. On the hind part of a dog or the kidneys of a horse the quantity was often less than 100 c.c. And on account of these great variations it is of little value to state on the record the absolute figures obtained from minute to minute. This would only render a comparison of the single trials more difficult.

I have, therefore, only stated how many per cent. the off-flowing quantity changed when the height of action of the single agents had been reached. As can be seen by a glance at the accompanying charts, this change was very trifling in some agents, and, again, quite enormous in others. In another column it is stated *how many milligrammes of the pharmacological agent had passed altogether*. Another column contains the *concentration of the latter in the blood, calculated for one litre*. Besides, it is also stated *how many minutes* the poisoning had lasted. All other statements of the charts speak for themselves.

Many readers of this paper will, after inspection of these charts, probably ask why with a number of pharmacological agents I had only instituted one or two experiments, which, of course, must be entirely insufficient to definitely settle the question of the influence of these agents on the blood-vessels. In reply to such queries I would say that experiments of this nature are enormously expensive and laborious, and take up a very great deal of time. The execution of the work embodied by these researches, for example, has occupied no less than three and one-half years. To mention some of its difficulties, I will state that for the transfusion of a single dog's thigh two dogs are always required, one of which, besides, is to be of a rather large size. For the transfusion in a rabbit three animals are likewise always required. Of the bought organs many were found to be cut, and had therefore to be thrown away; others, again, were not fresh enough, and gave no uniform current, while others, again, were insufficiently freed from blood, and consequently gave no current at all. I have not kept any record of the number of experiments which I had to abandon on account of intervening hemorrhages, of deficiency of blood, of stoppage of the current, of bad regulation of temperature, or, finally, on account of access of air, but I know their number is large.

It is known that every alteration of the vascular calibre caused by a pharmacological agent is followed later by a compensatory alteration, however slight it may be. I have not paid sufficient attention to these compensatory alterations to create a special column in my charts for them. At all events these compensatory variations did not prevent me from examining often four various agents on the same organ during two consecutive hours. It is a matter of course that the poisoned blood had to be thrown away in each instance. In experi-

menting with powerful poisons even the blood poured out after termination of the poisoning had to be thrown away, as it was found to still contain poison for some time.

Let us now pass to the interpretation and to a detailed discussion of the results obtained in these experiments.

Chloride of sodium added to the blood in small quantities causes no alterations while traversing the muscular tissues of the thigh. If, however, the blood is mixed in equal proportions with a physiological solution of chloride of sodium, the current rapidly decreases or wholly ceases. If a considerably higher

pressure is employed a regular flow can be again obtained, as I found from several experiments instituted in this manner on rabbits and productive of satisfactory results. That the majority of such experiments, however, failed cannot be ascribed to the chloride of sodium, but merely to the dilution of the blood by the added water. This I have proven by obtaining the same result by the addition of solutions of agents which by themselves increase the blood-current.* Chloride

ride of sodium is consequently by itself an indifferent agent in regard to muscular organs. This, however, does not hold true in reference to the kidney, where chloride of sodium, being a diuretic salt, increases the velocity of the blood-current. Urea was found to have a similar action, and in transfusions of the thigh appeared rather indifferent, while it increased the current considerably while passing through the kidney, as was previously ascertained by Abeles. I shall publish my observations with this and other diuretic agents in a subsequent paper. Caffeine probably belongs also to this category, as appears from the recent researches

of W. von Schroeder* on the diuretic virtues of this drug. Likewise indifferent were found to be glycogen, grape-sugar, kreatin, neutral phosphate of sodium, chlorate of potassium, iodate of sodium, bromate of sodium, bromide of sodium, and fluoride of sodium.

The antipyretics behaved very differently. Quinine, cinchona, chinoline, leucoline, salicylate of sodium, and oil of mustard caused a very considerable acceleration of the current. Resorcin appeared to increase the velocity only when given in large doses, while

* *Centralblatt f. die Med. Wiss.*, 1886, No. 26.

hydrochinon and antipyrin were wholly indifferent. Carbolic acid* even appeared to reduce the volume of the current.

There are numerous authors, particularly Maragliano,† who claim that antipyrin dilates the blood-vessels even in non-febrile persons. I have never been able to confirm this statement either in experiments with blood-pressure or in those with blood-transfusion, and I am consequently entitled to regard this claim as unproven, at least as far as the non-febrile organism is concerned. Kairin,‡ as stated above, behaves entirely differently. Besides, this drug caused, as pointed out first by E. Girat in 1883, and by Morochowez§ in 1884, the formation of considerable methæmoglobin. The other agents which can form methæmoglobin, such as ferrocyanide of potassium, nitrite of potassium, nitrite of amyl, and isonitrite of propyl, cause, like kairin, acceleration of the current. Agents which exercise an alterative influence on hæmoglobin, such as oxide of carbon in larger doses, sulphide of hydrogen (examined by Smirnoff),|| and prussic acid (examined by Mosso), increase likewise the volume of the current.

That oxide of carbon (after a preceding temporary contraction) causes a pronounced and lasting dilatation of blood-vessels has been proclaimed even before Mosso by Traube,¶ but has only been referred to central causes. Klebs,** moreover, regarded the vascular dilatation as the principal action of carbonic oxide, and recommended ergot as an antidote for it. A. Mayer†† evidently held the same view, for he obtained in hemicrania with carbonic oxide similar results as with nitrite of amyl.

The acceleration of the current caused by free hydrochloric acid probably refers also to its decomposing influence upon hæmoglobin, at least the blood becomes at once colored after its addition.

It is a very notable fact that alcohol and chloroform scarcely affect the velocity of the blood-current in isolated organs. The reduction of pressure obtained in experiments with blood-pressure sets in only after large doses, and is caused very clearly by a central vaso-motoric paralysis. Of all other narcotic agents, urethan is the most indifferent one, as could be readily inferred from Schmiedeberg's investigations. I have only examined urethan on kidneys where the diuretic action of the drug probably interfered with the determination of its action on the blood-vessels. I believe that on muscular organs the effects on the blood-current would have been equally negative.

Paraldehyde, acetal, hydrate of chloral, morphine, and extract of opium, on the other hand, cause a distinct acceleration of the current. The custom originating from Von Mering,‡‡ of employing hydrate of chloral in pharmacological analysis in order to cut off the vaso-motoric centre, is consequently not wholly correct, as an increased dose will cause also peripheral vaso-motoric paralysis together with the central paralysis. The same holds true of nitrite of amyl, the action of which is by Bernheim§§ and Filehne,||| however, regarded as central, while Brunton,¶¶ Wood,*** Richardson,††† Pick,‡‡‡ and others believe more in a peripheral causation.

Basing upon erroneous investigations of the pulse, Leyden and Eichhorst§§§§ believe that pilocarpine and nitrite of amyl reduce the tension of the vascular walls. In my researches both drugs acted just the contrary, and even in experiments made with blood-pressure I was unable to determine any resemblance between them.

Regarding cocaine, I find in nearly all non-pharmacological books the statement that it contracts|||| the vessels, and thus causes an augmentation of the pressure.

In my investigations I found cocaine with-

out influence upon the vessels. Apomorphine, which, according to O. Bergmeister and E. Ludwig,* acts upon the cornea like cocaine,—*i.e.*, contracts the vessels,—appeared in my experiments just like cocaine, indifferent in regard to peripheral vessels. Emetine and ergotine proved themselves to be wholly indifferent, which cannot be surprising regarding the latter drug, which my researches† have exposed as generally inert. Ergotinic acid, on the contrary, paralyzes not only the vasomotor centre, but also the peripheral vasomotoric nerves. Arsenic, strychnine, and nicotine were likewise wholly indifferent.

In regard to curare, it has often been said that it does not influence the blood-vessels, and that if a reduction of the pressure is at times observed, this is caused by an adulteration of the drug.

I cannot agree with this view, for I found that curarine obtained from Gehe—possessing a pure and strong curarine action—causes distinct vascular dilatation even in moderate doses. A similar action I obtained from Hofmeister's platinum‡ base and methylhydroxide of caffeine.§ The former, as is well known, has nearly all the effects of curarine, and the latter,|| like all hydroxides of methyl, acts curare-like in some respects.

The soluble double salts of metals did not by any means act all alike.

Iron was in small doses indifferent, while it increased the velocity of the current in larger ones. Platinum, bismuth, antimony, and manganese caused, even in small doses, a distinct acceleration of the current, while mercury and copper acted just the reverse. Still, these investigations ought to be made on various organs, and not, as in my experiments, exclusively on the kidney, as the specific action of the metals on this organ possibly interferes with the interpretation of the results obtained. The same holds true of iodide of lithium, bromide of lithium, and carbonate of lithium, which I could likewise only examine on the kidney, where they accelerated the blood-current, while I know nothing of their influence on the circulation in other organs.

Agents which, like carbonate of sodium, increase the alkalescence of the blood, increase the volume of the blood-current, while agents

like sulphuric acid, which decrease the alkalescence, decrease also the volume of the current. The action of hydrochloric acid has been referred to above. In the action of oxalic acid and its sodium salt the formation of emboli probably causes the decrease of the velocity of the blood.

The ethereal oils, of which I examined oil of turpentine, oil of peppermint, oil of aniseed, and oil of mustard, all act as accelerators of the blood-current.

Atropine causes an increase of the velocity of the off-flowing liquid, while muscarine and pilocarpine act just in the opposite manner, but not very intensely.

Chloride of barium, physostigmine, veratrine, antiarine, sabadilline, oleandrine, apocynine, scillaine, convallamarine, erythrophleine, Schmiedeberg's digitaline and helleboreïne acted so intensely and persistently as vascular contractors in various organs that I was forced to conclude that this action of these drugs makes itself likewise manifest upon man. The experience of my own practice in fact teaches me that that exhibition of preparations of digitalis is followed by an intense vascular contraction. I believe, moreover, that this contraction also occurs in the veins. In German therapeutic books I find a remarkable confusion regarding this point. Thus, Cloëtta, for example, says, even in the last edition of his text-book on therapeutics (p. 217), "Dilatation of the renal artery is one of the therapeutic effects of digitalis." The text-books published in the English language entertain likewise confused views in this respect. The view that the increase of blood-pressure caused by digitalis refers to a vascular contraction appeared early in pharmacological literature. Thus, we find it in the writing of Blake,¶ in 1839; Béranger Férande,** Oulmont†† and Segroux,‡‡ L. Brunton,§§ Briesemann,||| in 1867; Fothergill,¶¶ Gourvat,*** in 1871;

Ackermann,* in 1872; Brunton and A. B. Meyer,† in 1873.

But the proofs presented by these authors were so little convincing that Böhn† and Görz§ regarded them justly as unsatisfactory and critically untenable. Herman Köhler,|| in 1876, confirmed the views of the two latter observers. W. Williams showed later very clearly that the influence of substances belonging to the digitalis group upon the heart was sufficiently intense to bring about an extraordinary increase in blood-pressure by itself.

Quite available are also the researches of Henry H. Donaldson and Lewis T. Stevens¶ in Baltimore, and Sidney Ringer and Harrington Sainsbury** in London. These authors, who examined the influence of the digitalis group on the vessels (without the heart) of cold-blooded animals, did not content themselves with the unreliable microscopic examination of vessels, but resorted to transfusions in turtles. Reliable transfusions on organs of warm-blooded animals with the digitalis group do not appear to have been made as yet, for the researches of S. Talma and A. J. von der Weyde are little convincing.

In the continuation of my paper which I hope soon to publish, the researches of these authors will again be referred to.

I do not wish to draw from my own experiments the hasty conclusion that all members of the digitalis group cause a contraction of blood-vessels. Still, I must regard it as settled that *some members of this group produce a pronounced vascular contraction*. In the third part of this paper I shall treat of the members of the digitalis group having a different action.

The same action was manifested by the poison of toads in the transfusion of frogs,†† while in the transfusion of toads no alteration of the blood-volume was observed. Consequently, in the transfusion of toads with chloride of barium, helleboreine, and digitalis, in

doses which in frogs cause a very great reduction of the current, no influence upon the vessels could be made out. These animals, as Vulpian has pointed out, are nearly insusceptible against poisoning by substances belonging to the toad-poison group,—i.e., the digitalis group. (Only if the poison is administered in large doses intoxication ensues.) Quite in concord with this is the fact that the poisoning with toad-poison or helleboreine succeeds as well in the larvæ of toads as in those of frogs,—the larvæ of toads do not yet secrete any poison, and are consequently still unaccustomed to the action of this poison.

I have dwelt upon this difference of behavior between frogs and toads towards the substances of the digitalis group in blood-transfusions so explicitly because I regard it as the best proof that the reduction of the off-flowing quantity caused by these agents is not the result of mechanical or chemical alterations of the blood or of any other secondary effect, but of an especial physiological action, which of course is only absent in such animals the organs of which are accustomed to poisons of this kind. In the same manner, for example, the organs of morphiophages would not react to small doses of morphine as the organs of other persons, or, in other words, no dilatation of blood-vessels would ensue in the former.

The experiments on cold-blooded animals I have also utilized in order to determine whether in*transfusions of the whole animal the systolic cardiac stoppage sets in previous to the vascular contraction. If such be the case the vascular contraction would be a rather secondary phenomenon, would appear only when large doses are given, and would not take place *in vita*. In the determination of these points the results obtained of course differed according to whether the injection of the fluid (serum of rabbits) was sent in a centripetal (vena cava) or in a centrifugal (aorta) direction. In either case I obtained, however, provided the poison was added in a state of sufficient dilution, a distinct vascular contraction. From this fact I conclude that the vascular contraction caused by the digitalis group is not a post-mortem appearance, but belongs essentially to the physiological action of these drugs.

I need not add that I have often observed this phenomenon not only under the microscope but also with the unaided eye.

There was still to be determined whether the vascular contraction caused by digitalis is to be regarded as a muscular or as a nervous

†† Transfusions with blood, of course, and not with solutions of chloride of sodium, are here meant.

effect. I have attempted the solution of this difficult problem in many different ways. Thus I tetanized, after the appearance of vascular contraction during transfusion of a curarized hind portion of a dog, the sciatic nerve by means of faradic currents, a procedure which previous to the poisoning with helleboreine would have caused great vascular dilatation, exactly as in Bernstein's experiments. During the helleboreine-poisoning, however, this dilatation did not appear, which can only mean that on account of a musculo-vascular spasm the nervous dilatation did not set in. In this connection I beg to recall the action of muscarine on the physostigmine heart, which is likewise negative, although the two drugs are actually not antidotal to each other.

I also transfused cold organs, and found that the agents having a reputed nervous action, such as atropine, morphine, and hydrate of chloral, did not produce any effects, while helleboreine in a sufficient concentration acted very distinctly. It is unlikely that this vascular contraction taking place on cold organs is of nervous origin, for the nervous apparatus of warm-blooded animals do not react at a temperature of 15° to 20° C.

A muscular action, on the other hand, is well possible at so low a temperature.

I also transfused a kidney which in mid-summer had been exposed to decomposition for fifty hours, smelled rank, and showed a green-blue coloration; the transfusion was effected in the ordinary manner in the heat-box. While the most powerful agents of vascular dilatation produced no alteration in the current, I succeeded in this readily with the aid of convallamarine and helleboreine. It is scarcely possible that after a decomposition of fifty hours nervous apparatus should still be functionally active, while this can be well presumed in regard to the smooth muscular organs.

Another series of experiments was instituted with the liver. I have inserted in the charts several experiments, which were executed by transfusing the liver from the artery. The organ was then found to react to the poison like any other organ. In transfusions from the portal vein all poisons, with the sole exception of those belonging to the digitalis group, proved rather inert.* Still, I succeeded several times in obtaining a reduction of the velocity of the current by means of helleboreine and chloride of barium. Boehm†

appears to have obtained similar results with chloride of barium. These differential results, according to the starting-points of the transfusion,—the hepatic artery or the portal vein,—can only be explained by the assumption that the muscular coat is very feebly developed in the portal vein, but strongly so in the hepatic artery. I consequently believe that these experiments can at the same time be regarded as proofs that the digitalis action is as purely of a muscular nature in regard to the blood-vessels as it is in regard to the heart.

(To be continued.)

ON THE ABSENCE OF THE PATELLAR REFLEX IN HEALTH.

BY LESTER CURTIS, M.D., CHICAGO, ILL.

NOT long ago, purely as a matter of curiosity, I examined a patient, a lady of some 65 years of age, for the patellar reflex. I found it absent. The phenomenon to which this name has been given has received many synonymes, the most common of which are tendon reflex, knee-jerk, knee-phenomena, etc. It consists in an extension of the leg following a blow on the patellar tendon. Similar phenomena occur sometimes following irritation of other tendons. The phenomenon is spoken of by writers in such a way as to lead the reader to suppose that it is always present in health. Indeed, most of them state distinctly that this is the case. Althaus, in a recent admirable work, says that he has never found it absent in a healthy person, "except in the two extremes of life. It is difficult or impossible to elicit it in some children before they have learned to walk, and also in decrepit old persons, where there appears to be no particular form of spinal disease" ("Sclerosis of Spinal Cord," p. 139). A. Charlton Bastian says, "The knee-jerk occurs in health, so that it is its absence which is of principal significance" (Quain's "Dict. of Med.," p. 1458). Gower speaks of the phenomenon as occurring in health, but does not refer to any exception ("Diseases of Nervous System"). Erb, one of the first to describe the phenomenon, refers to no exception to its occurrence in health, although he remarks in a general way, and in another place, that in some cases the reflexes are difficult to obtain (Ziemssen's "Cyclopædia of Practice of Medicine," vol. xiii., Wood's ed.). Strümpel says that "after a blow on the tendon there occurs, almost without exception in a healthy person, a more

* *Schmiedeberg's Archiv*, vol. iii., 1875, p. 216.

† Mosso's results do not agree with those of Boehm.

or less active contraction of the quadriceps by which the leg is extended" (*"Lehrbuch der Speciellen Pathologie und Therapie,"* vol. ii. p. 64). The "almost," etc., here is of course a mere saving clause in case of contradiction.

Works on general practice which, without being very accurate or minute, reflect the drift of public opinion in the profession, are very nearly unanimous in the same direction. Loomis, in speaking of locomotor ataxia, says, "The abolition of the patellar tendon reflex is one of the diagnostic signs of the disease." Eichorst, in *"Wood's Library,"* says, "This is one of the earliest symptoms of ataxia. Its appearance indicates the existence of foci of degeneration in the external portions of the posterior columns in the upper lumbar region of its transition to the dorsal region." Such quotations might be multiplied indefinitely. It is plain, therefore, that the presence or absence of this symptom deserves attention.

Observers are not agreed as to the causation of this phenomenon. The prevalent opinion, however, is that of Erb, that it is a true reflex produced by an irritation of the sensitive nerves of the tendon, which is conveyed to the spinal cord through the posterior roots, and to the motor cells of the anterior horns, where a motor impulse arises, which is conveyed to the muscle. "The reflex centre is in the lumbar region of the cord, in the parts corresponding to the second, third, and fourth lumbar nerves" (Bramwell).

The phenomenon occurs quite independently of the brain, and must occur so long as the machinery by which it is produced is in proper order, just as certainly as the pupil responds to light, or any other of the ordinary reflex phenomena, the disturbance which interferes with the production of the phenomena being of course in the large majority of instances some disturbance in the spinal segment. Prominent among these is the sclerosis of the posterior columns, constituting locomotor ataxia on the one hand and degeneration of the motor cells on the other.

But the person mentioned above is healthy in all respects, and especially so as regards the spinal cord. She is an artist, and, in skill of hand and accuracy of eye, few, even among young professionals, are her equal. She is a good walker, and almost as sure of foot as in her younger days. So far as I could learn, she has never had the slightest symptom that could be considered as indicating disease of the cord. The examination, however, is open to criticism. The percussion of the tendon

was done over the clothing, and it is possible that it was not sharp enough to irritate the nerves of the tendon sufficiently, or possibly there may have been an active contraction of the hamstring muscles sufficient to prevent the reflex, though the percussion was repeated many times when she was not looking. I could hardly ask her to allow an examination thorough enough to remove all these doubts, without some other reason than the gratification of mere curiosity.

Althaus says, "The phenomenon may be obtained when the patient is sitting in a chair, and crosses one leg over the other; but, where the legs are short and stout, it is better to let him sit on the table, with the legs hanging down. Where the patient is examined in bed, the limb should be raised by the observer passing his left hand underneath the thigh just above the knee, and giving the tap with the right hand. In general it is not necessary for the patient to be undressed, but where the result is doubtful it is always best to strike the bare skin over the tendon, and it may be useful, especially where the patient appears nervous and excitable, to have his eyes bandaged, so that any interference on his part with the production of the phenomenon may be prevented" (p. 132).

Strümpel says, "In order to call forth the symptom, it is specially necessary that the person investigated shall avoid all active tension of the muscles of the leg, especially the extensor cruris" (p. 64).

I have seen sometimes, from the hands of persons who would feel hurt if they were called clumsy, so heavy a blow given as to produce a vibration that might be mistaken for the reflex phenomenon. The blow should be sharp and quick, from something not too heavy, so as to give an irritation at some depth without jarring the limb. A vigorous contraction of the muscles of the arms will increase the reflex in doubtful cases.

I have examined a good many healthy persons for this symptom since it was first described by Westphal, and have frequently found it absent. These examinations, however, have usually been deficient in some point necessary for scientific completeness. Either precaution was not taken to be sure that the blow was sharp enough to produce sufficient irritation, or the possibility of an involuntary contraction of the muscle was not provided against beyond the possibility of doubt, or the presence of some slight symptom of tabes was not carefully enough inquired into to prevent the possibility of doubt. In many of these

cases, also, no memoranda were made, so that they could be referred to again, and many of the phenomena have slipped from my memory altogether, or the details have become so obscure as to be valueless. But I have one case in which all these conditions have been fulfilled, and that is myself. I have been repeatedly examined for the tendon reflex during the last ten years under circumstances which will admit of no doubt, and the reflex has always been absent. I have never had a symptom of tabes, or any other spinal trouble, and I am sure that those who know me will agree that I have at least as much endurance of fatigue, and as good control of my muscles, as the average healthy man.

It is possible, then, for the reflex to be absent in health, and probably in a large percentage of cases. The persons in whom I have found the reflex absent are all persons of considerable muscular power and of a high degree of tonicity of the muscles, and especially persons of considerable inhibitory power, persons who do not lose self-control by any sudden shock. I suspect that the majority of those who have the reflex are persons of weak nerves and undisciplined muscles, who would scream if some one jumped out upon them from a dark passage, or would be unnerved by a sudden danger,—such persons would be the ones likely to come under the observation of hospital physicians. I doubt whether a hunter who retained his presence of mind upon seeing a grizzly bear suddenly rushing out upon him from a thicket would have much of the reflex, while another who had buck fever upon sight of a deer probably would have it well marked. It certainly is exaggerated in hysterical and neurasthenic cases in whom the inhibitory power is weak. The absence of the reflex is considered to be one of the very earliest symptoms of locomotor ataxia. Strümpel says, "The loss of the patellar reflex is the most constant of all the known symptoms of tabes; it is, indeed, observable so early that the time of its appearance can scarcely ever be determined" (p. 201). And, again, p. 211, "A symptom almost constant and of the highest diagnostic value is the loss of the tendon reflexes, especially the patellar reflex. As already mentioned, the extinction of this reflex is one of the earliest symptoms of the disease, which is of the very greatest significance," etc. It is often almost the only means of distinguishing between locomotor ataxia and certain conditions occurring in neurasthenia and in other affections which may simulate locomotor ataxia, and its im-

portance as a symptom is growing in favor. But if these observations are correct it loses immensely in value. The temptation to theorize is strong, but I will refrain, and only call attention to a recent article by Prof. Hirt in the *Berliner Klinische Wochenschrift* for March 8, 1886, in which he describes three cases of locomotor ataxia with retained patellar reflex.

After some general remarks, he describes the cases as follows:

"On the 25th of April, 1884, Moriz W., a moulder, from Upper Silesia, came under treatment at my polyclinic. The patient stated that he was 57 years old, and that when a soldier, at the age of twenty-one, he had had a chancre, with resulting throat-affection. In early youth, from his tenth to his fifteenth year, he had been an enthusiastic fisherman, and had stood for hours at a time with bare feet in very cold water. His present disease dated from the year 1877, and was characterized, according to his account, by great weakness and pain in the legs, difficulty of breathing, trouble in urination and defecation, impotence. The history of the family was without importance." "On examination it was found that the coarse strength of the muscles was well retained everywhere, and that in no department was atrophy to be discovered. The sensibility was altered in many ways,—first, cutaneous analgesia could be demonstrated over the whole body with the exception of the face and the portion of the head covered by hair. For light pressure the sensibility was, on the contrary, retained, and there were in the neighborhood of both sciatic regions hyperæsthetic zones. Distinct *girdle feeling*, sense of temperature for small differences retained, muscular sense altered. With closed eyes the patient could give no information concerning the position of his legs in bed, and did not know whether the one or the other was carefully raised. Romberg's symptom, ataxic gait. *Patellar reflex on both sides easily and plainly produced*, also the plantar and abdominal reflex. Cremaster reflex on both sides gone. Reflex fixation of the pupil and affection of the eye-muscle could not be demonstrated. Patient had never suffered with diplopia. Pupil of moderate size, reacts very slowly but distinctly to light and accommodative impulse. Paresis of the bladder, unconscious passage of the urine by drops by the impulse of coughing, voiding very slowly, not without burning, boring pain in the urethra. No gastric and no laryngeal crises. Appetite and digestion tolerable; tongue normal; no hemiatrophy." "The circum-

stances which have been represented continued essentially unchanged during a year. In September, 1885, the shooting, lancinating pains were very troublesome to the patient. At the end of November the patient became ill of a double pneumonia, to which he fell a victim on the 17th of December." "Autopsy only partially allowed. Opening of the chest and abdominal cavities was refused by the relatives. On opening the skull, there existed in the brain only a slight congestion of the pia, and its vessels were not abnormal. Brain-substance of normal consistence, in no way changed pathologically. On removal of the spinal cord there was found in fresh transverse section, plainly demonstrable (even macroscopically), gray coloration, and atrophy of the posterior columns. This degeneration could be followed into the middle of the cervical cord, increased in the middle of the dorsal cord, and here the posterior gray columns appeared atrophic. The transition from the dorsal to the lumbar cord appeared, so far as might be judged from the macroscopic appearances, less degenerated. In the middle portion of the lumbar cord, on the contrary, the degenerative process was most distinctly developed. Here also there was atrophy of the posterior gray horns. In teased preparations there were richly scattered degenerated portions, fat-granules, branched cells, and corpora amylacea.

"In what way the degeneration of the single parts spread itself out upon Goll's columns, how Charcot's bandolettes are thereby affected, and whether the division into fields, as Strümpel has described, exists, cannot of course be recognized in fresh or frozen preparations. The description of the single sections of the cord I reserve until after its complete hardening. Here I shall only state provisionally the presence of sclerosis of the posterior columns, so far as it is possible to prove it macroscopically. Nothing was to be noticed macroscopically of a contemporaneous degeneration of the lateral columns or of the direct cerebellar tract.

"The second case concerns the laboring woman Rosina G., still living, from Dürrgoy near Breslau. She was repeatedly examined by me and presented to my clinic. The patient, who was most kindly assigned to me by my colleague, Dr. Magnus, is 46 years old, married since her fourteenth year, has borne ten children, eight of whom died early. She has not been well for fifteen years. Her illness began with active headache, which was especially located in the back of the head, and

lasted for years. Soon the feeling of being slightly tired was added to this, so that the patient has for just ten years been very weak on her legs. Five or six years ago double vision occurred, which continued a few months and then disappeared without, up to the present time, returning. Soon frequent active feeling of dizziness. Gradually there developed, first on the right, then on the left side, an optic atrophy; right eye totally amaurotic, left, a great degree of lowering of acuteness of sight. In the year 1882 there appeared for the first time sensible phenomena of irritation in the form of a girdle sensation and severe lancinating pains; at last they were so tormenting that in the year 1884 they sent the patient to bed for weeks at a time. At the same time (1884) there developed urinary difficulty; the water was passed very slowly, almost drop by drop, only if the bladder was in some way strongly filled. By a slight impulse of coughing a small quantity of urine was passed unconsciously. This paresis of the bladder exists still. For the last eight years there has been very frequent and often very severe vomiting of quantities of watery fluid; this symptom is connected with a feeling of dizziness." "At the first examination, May 13, 1885, it was shown that the patient was a strong, robust-appearing person who showed a good condition of nutrition. The investigation of cranial nerves showed nothing abnormal in the olfactory, oculo-motor, abducens, and facial. The right optic nerve showed a high degree, the left a beginning, atrophy. The right half of the face is anæsthetic for all sorts of feeling. The right half of the tongue is not atrophied; it responds neither to sensitive nor taste irritations. The left half of the face and the tongue are normal in relation to sensibility. By examination of the sensitiveness of the rest of the body a difference between right and left was not to be perceived, but there was loss of sensibility to pain in both hands and both legs and feet. The muscular sense is changed. Romberg's symptom. Lying with closed eyes the patient could not tell the position of her legs. Disturbances of motion not perceived. Ataxia not present. Coarse strength of upper and lower extremities normal. By examination of the reflexes, it appears that the patellar reflexes of both sides are present, plain and in normal strength. An increase of the same is just as certainly excluded as a diminution. On questioning the patient, she said that the intense tired feeling and especially the painful vomiting which occurred

daily caused her to come under medical treatment." "The symptoms which have been described have continued up to this time almost unchanged, as I stated several days ago. Damage to the left eye also, as the result of optic atrophy, threatens.

"Finally, the third case concerns a letter-carrier, August W., from Sorgau, in Silesia, for whom I must thank my colleague, Thomas, in Freiburg. The history of his disease is briefly as follows: Fourteen years ago a chancre with secondary phenomena, violent pains in the legs, frightful pain as if pierced with a red-hot knife. Double vision lasting for one year and still existing, severe dizziness in the dark, slight tired feeling, no bladder-symptoms, virility retained, no gastric crises." "The investigation (October 27, 1885) gives: Strong, well-nourished man, with remarkably painful expression of the face, ptosis dextra, paralysis of the left abducens, optic of both sides normal, in the regions of the facial and hypoglossal nothing remarkable, no hemiatrophy of the tongue, sensibility of the face as well as taste normal. On the upper extremity, here and there, cutaneous analgesia; tactile and temperature sensation in the hands diminished. Patient cannot fasten small buttons at his toilet because he does not feel them plainly, widespread cutaneous analgesia of the feet, Romberg's symptom, walking with closed eyes impossible, *patellar reflex of both sides normal*, on the left perhaps somewhat increased. Cremaster and intestinal reflexes indistinct, plantar reflex active, diplopia and lancinating pain still present. A communication has been lately received from Dr. Thomas, according to which the patient has been for some time weak and bedridden. It was stated on the 24th of January that no change had occurred in the above phenomena." "That we have to do with *tabes dorsalis* in the two last cases (the proof of the first is furnished) appears to me to be without doubt. In Mrs. G. the degeneration has extended farther upwards than usual, and has attacked the ascending sensitive root of the right trigeminus. Perhaps the gastric crises which are here so specially distinct may be traced to an affection of the nucleus of the vagus, as Buzzard has supposed. In other respects the course of the case is typical. The same holds true for the letter-carrier, W., whose complex symptoms appear to render the diagnosis undoubted.

The retention of the patellar reflexes is the only thing remarkable in all three cases, and it is a question whether the first case established by

the autopsy is sufficient to make untenable the view of the localization of the phenomenon which has up to this time been accepted. *A priori*, I might doubt whether this is the case, for in an otherwise extremely extensive degeneration in the posterior columns, exactly the place which has been considered and described by Westphal and others as the anatomical site of the patellar reflexes can remain intact. I am so much the more inclined to this view, as in another case of *tabes* out of my private practice, which I am not at liberty to publish, *the patellar reflex on one side is retained*, while on the other it disappeared a year and a half ago.

"Here it is in the highest degree probable that we have to do with a one-sided degeneration of a portion of the posterior column. In any case I must refrain from a decided opinion until the undertaking of the microscopic investigation of case W.

"In conclusion, I remark that a few days ago I had an opportunity to describe my case orally to Privy Councillor Westphal. He explained to me, while at the same time demonstrating several symptoms, that he also was preparing observations on two cases belonging to this place, the publication of which had been delayed on account of illness."

35 UNIVERSITY PLACE.

THE TREATMENT OF BRIGHT'S DISEASES.*

BY F. A. BURRALL, M.D.

THE treatment of Bright's diseases has been partly derived from a knowledge of the pathology of these diseases indicated by post-mortem appearances, partly from examinations of the urine while the morbid changes were in progress, and some remedial measures are still empirical. The classifications of Bright's diseases are even yet so various and unsettled that, in considering the therapeutics of the disorders which come under this general appellation, it seems the most practical and direct method to subdivide all the lesions into the two varieties of *acute* and *chronic*, and refer separately to such remedies as are believed to be specially indicated in one form of renal degeneration more than in another. The treatment of complications also calls for a brief reference.

* Read before the Section on Materia Medica and Therapeutics, New York Academy of Medicine, December 15, 1886.

As a type of acute Bright's disease the parenchymatous form is most marked. This variety has also been termed croupal, catarrhal, desquamative, and tubal. Here there is an abnormal increase of blood in the organ, and the tubes are choked with casts and disintegrated tubular products. As a rule, the urine is diminished and albuminous, and there is more or less oedema, usually of the eyelids or face. These are the prominent pathological conditions present. As a result there is varying febrile disturbance, blood-poisoning caused by retained renal excreta is taking place, and the blood is also being deprived of its nutritious elements. The indications are to *rest the inflamed organs; remove retained excreta and wash out the obstructed tubes; restore the kidneys to their normal condition*, and prevent recurrence of attacks. The remedial measures are,—*rest* in bed in a room with a temperature of from 70° to 75°, *dry cups* to the loins, *sufficient diaphoresis, diuretics*, and suitable *cathartics* if constipation is present.

Rest is the first indication whenever inflammatory symptoms are present. By it the circulation is calmed and equalized, the nerves are soothed, and rest in bed surrounded by a warm temperature secures better action of the skin and places the patient under favorable circumstances for the application of remedies. Rest also diminishes the exudation of albumen.

Dry cupping to the loins relieves renal congestion and favors diuresis. By this temporary abstraction of blood into the subcutaneous capillaries a diminished pressure is produced in the lumbar arteries which supply the integuments of the loins, and this diverts a certain amount of blood from the renal arteries. The object of the cupping is to draw the blood into the capillaries, in order that it may be taken up and removed by the veins. The cups should be removed as soon as filled, and reapplied. No cups are better for the application of this remedy than the ordinary tumbler, which is always at hand. A good method of applying these is to dampen the bottom of the glass, so that the piece of loose dry cotton which is to occupy the bottom of the glass does not fall out when the cup is used. The skin is to be moistened with warm water, and the glass applied instantly after the cotton is lighted, when an excellent vacuum is produced and the integument rises into the glass. The cupping-glass with rubber bulb is also a convenient instrument for dry cupping. It has seemed to me that when the blood under the cups remained purple and stagnant

after their removal, this indicated marked renal congestion, and that the reddened integument more quickly recovered its color in proportion as those symptoms disappeared, which implied the presence of an excessive amount of blood in the kidney. I have not observed this sufficiently to be sure of the fact, but it was suggested by observation in several cases. Hot fomentations to the loins after the cups have been removed also relieve renal congestion.

There is a diversity of opinion with regard to the use of the hot-air bath. It has been said that by promoting perspiration so much fluid is carried away through the skin that an insufficient quantity remains to wash out the obstructed uriniferous tubes. This objection has been met by the reply that when there is much dropsical effusion free perspiration relieves renal congestion and promotes renal circulation by diminishing pressure in the renal vessels. As a result there is a more copious flow of urine. The amount of fluid lost by perspiration can be readily supplied by ingestion of water. The sympathy or supplementary relations between the skin and the kidney are well known, and it is admitted that the skin is an important organ for the elimination of urea. Hence, when the kidney is unable to perform this eliminative function, it would seem rational to stimulate the functions of the skin. My experience leads me to regard the *intermittent* hot-air bath as beneficial, but it is an agent better adapted to some cases than others. I think it is of service in the early part of an attack of nephritis and in impending convulsions, while if a patient is what is termed water-logged and anæmic it is less useful. Sometimes it produces great discomfort and no diaphoresis, and here it should be discontinued. Its use should be accompanied by the free drinking of water. The pack is somewhat similar in its action to the hot-air bath, but is often more soothing.

Stimulating *diuretics* are much less used than formerly in the treatment of this variety of Bright's diseases, since they are more likely to be injurious than beneficial, by increasing the congestion of the kidneys, which is already excessive. What is desired is to cause a sufficient amount of fluid to pass through the kidneys to wash out the retained excreta from the tubes. Water seeks the kidneys as one of its most usual channels of elimination, and this should be drunk freely. The water from some of the mineral springs in this country, such as the Bethesda, or Buffalo lithia, or Poland, also have an excellent diuretic action;

and when, as in some instances, there is an excess of uric acid in the blood, those waters which contain lithia are especially indicated. When, on examining the urine, we find numerous rough crystals of uric acid, we naturally infer that the aggregate effect of these minute jagged particles must be to irritate the delicate structures over which they pass, and that this irritation should be removed by dissolving them. Therefore there is a positive indication for a free use of water, or the dilute alkaline mineral waters, especially those containing lithia or potassium. Why waters which contain so small a proportion of salines should be preferable to pure water is not so well understood, but clinically I think this is demonstrated.

Water containing a small proportion of the bitartrate of potassium is sometimes used instead of the natural spring waters. To insure the diuretic action of salines their specific gravity should be less than 1028,—that is, less than that of the blood.

The drug most used in the therapeutics of Bright's disease for its diuretic action is digitalis, and the infusion is generally preferred. Digitalis does not possess intrinsic diuretic properties, yet its use is followed by marked excretion of urine. Long before its method of action was understood, it was regarded as the best remedy for that variety of renal disease in which there is congestion and tubal obstruction. Under such circumstances, in the stronger light of modern investigation, it is believed that "the contraction of the capillaries causes a greater quantity of blood to accumulate in the arteries, the difference of pressure between the arteries and veins will increase in favor of the former, and the blood will rush through the capillaries at a greater pace, and, owing to the pressure within the veins being lessened, the dropsical effusions will return to the venous system, and at the same time the watery constituents of the blood will increase and cause great diuresis." (Ackerman.)

The infusion is given in doses of from a dessertspoonful to a tablespoonful, three times daily, oftener in emergencies, and Stillé and Maisch direct that when it begins to act upon the kidneys, stomach, pulse, or bowels, the medicine should be discontinued or the dose greatly lessened. After diuresis has commenced, a dessertspoonful of the infusion, two or three times daily, promotes continuous diuresis. Some physicians use this drug much more freely than others, and it would seem as if the old idea of cumulative dangerous action

were mythical. It is probable, however, that its use is not devoid of danger, and we are advised that "the first symptom which warns us to omit the drug is irregularity in the rhythm of the pulse." (Binz.)

As the acute symptoms subside, or even earlier, the use of iron enters into the therapeutics of this renal disease. Iron is believed to act by checking hæmaturia, diminishing the general anæmia, and lessening the amount of albumen and casts. Its action is apparently general and local, although iron is said not to be detected in the urine after its use. The tincture of the muriate of iron is the preparation generally used. A point connected with the administration of this drug is its action upon the teeth. Recent experiments have shown that the enamel of teeth, when subjected to a watery solution of tincture of iron, is eroded, and this effect is prevented when the tincture is added to syrup or alcohol. For children the syrup of tolu is an excellent vehicle. A satisfactory method of preventing the injurious action of this medicine upon the teeth is to direct that the patient should rinse the mouth after the dose with a solution of bicarbonate of sodium. Other preparations of iron, such as the liquor ferri oxysulphatis, the syrup of the phosphate, "Basham's mixture," or the tincture of the chloride in combination with acetic acid and ammonia, are also recommended.

Cathartics may be of service in acute Bright's diseases, when there is an obstruction of the portal circulation and unassimilated nutriment is passing off through the kidneys, making the urine dense and irritating with urates or uric acid. It is desirable that all fluid passing through the kidney should be bland, and a cathartic which acts upon the liver promotes excretion of waste products through the intestinal canal. As a rule, drastic cathartics are not much used in acute Bright's disease. They are sometimes of temporary service in the emergency of acute uræmia, when $\frac{1}{4}$ grain of elaterium or 2 drops of croton oil will divert the serum, and with it the poisons which it contains, into the intestinal canal, and also by relieving renal congestion promote diuresis. The free catharsis produced by *pulvis purgans* is also of similar service.

For restoring the kidney to its normal condition a steady continuance in remedies and careful attention to diet and hygiene are requisite. The iron should be given regularly, with occasional intermissions, if constipation or plethora or nausea render it neces-

sary. Dry cups, applied twice or three times daily, ward off renal congestion, and digitalis promotes diuresis. A pad of flannel, worn over the loins, not thick enough to produce constant perspiration, but of sufficient thickness to insure warmth and protection against sudden chilling, is a most useful remedy. An interval is often left by the modern style of dress between the waistcoat and pantaloons, which exposes the loins to draughts and checks of perspiration, and if we notice the kidneys post mortem, we see how carefully nature has endeavored to protect them by a skilful covering of fat. It is, no doubt, of great importance to guard the loins against draughts of air and sudden changes of temperature.

Although some experiments have seemed to show that a milk diet is followed by the appearance of albumen in the urine, there is no doubt that there is no article of food which is more approved by physicians in this disease than skimmed or unskimmed cows' milk. Milk is bland, possesses the necessary elements of nutrition, and aids diuresis. With a milk diet there is less urea furnished to the blood. Milk is not a beverage but a food, and should be drunk slowly and well mixed with the saliva before swallowing. There are some patients who think they cannot take milk. If this condition, real or imaginary as it may be, is insurmountable, some other bland diet agreeable to the patient should be chosen, with the avoidance of strong tea, coffee, and alcohol. Koumyss is sometimes useful. *Too much* solid animal food is not allowable, since it furnishes an excessive nitrogenous basis for the formation of urea. Perfect assimilation is to be aimed at in selection of diet.

When patients are able, and to complete the cure of acute Bright's diseases, as well as to insure immunity from future attacks, residence for a time in a warm, dry, equable climate is of the greatest service. Meantime, the cupping, iron, and a careful attention to diet and hygiene should be maintained, and the urine examined at frequent intervals for the purpose of watching the progress of the disease and applying suitable remedies.

The treatment of *chronic nephritis* may be summarized as requiring *the improvement of general nutrition, the avoidance of acute attacks, and the treatment of symptoms and complications*. If we were asked to select two remedial measures in preference to all others, I think we should choose freedom from care, and residence in a dry, warm, equable climate. Where these conditions are even approximated, we

see life indefinitely prolonged in certain patients. But they are conditions difficult to attain. Care is the lot of humanity, and many sufferers from Bright's diseases are held to the various labors of life by domestic or financial ties. Such should, as far as may be, lead careful lives, and avoid cold, fatigue, and errors of diet. The clothing should be warm enough to prevent chilliness, but not so thick as to cause constant perspiration, and the feet should be kept dry. Milk is a most desirable diet in many cases, and can be made more palatable by the addition of a very small quantity of salt, or it may be peptonized, and the amount taken varies from two and one-half to four quarts daily, with which may be used a few ounces of farinaceous food. Light wines may be used judiciously in some cases of chronic nephritis. While there is remaining renal congestion, or scanty urine, or indications of choked tubules, dry cups and digitalis, with the moderately alkaline waters, should be used. Iron is indicated to avert the anæmia usually present. Diuretics are not required in the case of the cirrhotic or waxy, or in the atrophic stage of the parenchymatous, form of kidney-disease, except as an occasional scantiness of urine may occur, and some authorities hold that iron does not agree with patients who have the cirrhotic kidney, as well as cod-liver oil with the hypophosphites.

Some physicians think very highly of the bichloride of mercury in doses of from $\frac{1}{10}$ to $\frac{1}{8}$ of grain as a remedy in interstitial nephritis (cirrhotic kidney) and in the chronic form of parenchymatous variety of the disease.

Quinine, cod-liver oil, and nux vomica are given as tonics when the indications point to their use.

In the amyloid or waxy kidney, the iodide of potassium and mercury in small doses are recommended if any syphilitic history can be discovered, and the iodide of potassium, with cod-liver oil or the iodide of iron, are said to be serviceable when debility is present. Nitroglycerin has been found of service when increased vascular tension existed. Opium or morphine are remedies which are warmly endorsed on the one hand and regarded with caution on the other. Dickinson says that opium, which is dangerous in case of the granular kidney, may be freely used in the diarrhoea which accompanies waxy disease.

There are several plans of treatment for the *acute uræmia* and convulsions which may appear during the progress of any of the varieties of Bright's diseases. One method is

to relieve the system of retained urinary excreta by acting on the skin and bowels, and to quiet nervous excitability. Croton oil, jaborandi, or the hydrochlorate of pilocarpine, or elaterium, even blood-letting, and the hot-air bath or pack, and chloral to calm the nerves, represent the chief remedial agents under this head. On the other hand, opium or morphine are regarded as the remedies to be chiefly relied upon. The infusion of digitalis is to be given at the same time in $\frac{1}{2}$ -ounce doses every three hours until its specific effects are produced. It seems to me that all of these remedies may have their use in certain cases, but there is a feeling among many physicians that opium and pilocarpine should be employed with care. Dry cups to the chest are one of the best remedies in pulmonary oedema, and when the chest is covered with them prompt relief generally follows. For obstinate anasarca incisions into the cellular tissue are sometimes practised with much benefit, relieving swelling and promoting diuresis. It is advisable to bathe the incisions with an antiseptic lotion.

It is difficult to classify the principal remedies in use in Bright's diseases, since many fulfil several functions, but the following is an attempted approximation to indicate their chief effects:

Indirect Diuretics.—Digitalis, dry cups, cannabis indica (when hæmaturia is present), caffeine.

Direct Diuretics.—Potassæ bitart., scoparius, water and the alkaline spring-waters, tannate of sodium (gr. xx to xxx), apocynum cannabinum.

Diaphoretics.—Hot-air bath, the pack, warm baths, jaborandi, pilocarpine.

Tonics.—Quinine, iron, cod-liver oil, strychnine.

Medicines which diminish Albumen.—Gallic acid, hydrastis, iron, chloride of gold, fuchsin, and rosanilin.

Promoters of Tissue Metamorphosis (Metabolists).—Hyd. bichlorid., chloride of gold and sodium, potassii iodid., liq. potassæ (largely diluted).

Antispasmodics.—Chloral hydrate, opium, potassii bromid., hyd. c. creta (to prevent nausea).

Cathartics.—Elaterium and croton oil (hydragogue), euonymus (cholagogue), podophyllin (cholagogue), pulvis purgans, hyd. c. creta (laxative, Satterthwaite), 3 to 5 grs. daily in cirrhotic kidney.

The course of Bright's diseases is beset

with complications, and many cases require most careful watching. The treatment of them is partly that of the basic disease itself, and besides, the general remedies indicated for the various intercurrent maladies. Headache, nausea, gastritis, cardiac hypertrophy, serous inflammations, pneumonia, may all interfere with the comfort or partial health of the patient, and aggravate his sufferings or shorten his disease. They are more or less susceptible of alleviation.

In conclusion, the treatment of Bright's diseases, as of all others, is based upon our knowledge of their nature, and we are struck with the apparent deception connected with renal semeiology. It is not severe pain in the organ itself, but a blurred vision, an oedematous membrum tympani, hemicrania, a puffy eyelid, slight syncope, apparent dyspepsia, nervousness, slight enuresis, which are the signals of a distant morbid process. Often such symptoms are treated in vain, because the real disease is overlooked. It is well in making our diagnosis of any disease to bear these renal peculiarities always in mind. Then our treatment of diseases which seem to have no connection with renal disturbances will, more often than we would suppose, be directed to improving the functions of a diseased kidney.

ON LIGATION OF THE POPLITEAL ARTERY IN ELEPHANTIASIS OF THE LEG.

BY EMMANUEL DAGNINO, A.M., M.D., CARACAS, VENEZUELA.*

I.

IS there any etiological difference between the elephantiasis of the Greeks and that of the Arabians? Though in the actual state of science the general and constitutional causes of the one and of the other disease cannot be ascertained in a precise manner, perhaps it may be assumed that though both classes of elephantiasis, presenting the hypergenesis and proliferation of certain anatomical elements, cause the hypertrophy of some tissues, still they are not the same disease, the same nosological entity. Tuberculous leprosy (in all its varieties) is undoubtedly united to certain alterations of the spinal marrow.

* Professor of Pathology in the University of Venezuela, Corresponding Editor of the *Annual of the Universal Medical Sciences*, etc.

The experiments of Vulpian on the spinal cord, producing affections of the skin somewhat similar to the cutaneous manifestations of general elephantiasis, command reserve in regard to the diagnosis of some cases, and bring to the mind the conviction that general elephantiasis is undoubtedly allied to spinal alterations. The anæsthesia and hyperæsthesia, the atrophy and hypertrophy of a few tissues, that form the anatomical and pathological symptomatology of patients suffering from elephantiasis, are signs linked to the alterations of the nerves that animate and nourish those parts. This view, based on physiology and experimental physiology, that attributes to the spinal marrow and to the great sympathetic nerve so important and essential a part in that terrible illness, not thoroughly studied until now, would satisfactorily explain the influence of syphilis in producing tuberculous leprosy; for though it is true that in many cases, as I have been able to ascertain, the evident cause of that disease is the sudden cooling of the body when sweating, also it is true that in others, and very commonly, syphilis is the only cause to which I have been able to ascribe elephantiasis, without doubting in the least that, respecting others, contagion and hereditary disposition ought to be taken into consideration.

And now, is not visceral syphilis clearly demonstrated? It has also been proved that there are various syphilitic manifestations (sclerosis, sclerosis with patches and alterations of the gray and white nerve substances in different parts), bringing, as a consequence, functional and organic disorders, to be seen in the groups of symptoms characteristic of elephantiasis. In the history of many patients syphilis plays an important part. My opinion is that syphilis can bring about elephantiasis, just as suppression of sweat by water is a very frequent cause of it; in fact, probably the most common in warm climates. Among many cases I shall relate a very recent one:

N. N., a native of San Rafael, applied for treatment in the Hospital of the Casa de Beneficencia. The physician, Dr. Francisco Suarez, desired me to examine this patient, whose only sickness was blindness. He was a man in good health, of about 45 years, married, with several children, all healthy. For about two years the patient could not apply himself to work; he was a laborer. He had two capsulo-lenticular cataracts, and his eyes were in a satisfactory state. There being neither

pains, nor synechia, nor anything that might point out an unfavorable prognosis, I advised the operation of lineal extraction. Both eyes were equally capable of being operated on. I performed both operations, with the interval of ten days, in the presence of Dr. Suarez, the physician of the hospital, Dr. C. L. Sanchez, Dr. Giro, a Cuban, and the assistants of the same hospital. Both operations had the most brilliant success, and the patient left the place with his sight in an excellent state, and not one of the physicians could observe in him the least morbid appearance.

A year and a half ago a man, considered to be suffering from elephantiasis, went to my clinic of the Hospital of Chiquinquirá. Trying to form a complete anamnesis by a methodical inquiry, I found that he had never suffered from syphilis, and that the only serious thing he had experienced during his life was an operation that *I had* performed. Then I knew that the unfortunate man I had before me was the same one whose cataracts I had extracted, and who was then enjoying perfect sight. Far better would it have been for him never to have recovered his sight; for as soon as he left the hospital he had gone to his native village, and applied himself to mining to earn his family's livelihood; and being once busily occupied in his labor, all in a sweat and shirtless, received the rain that fell on his bare back. From that very day he felt unwell, and, little by little, supervened the symptoms and signs of this disease. After about three years and a half he was affected with elephantiasis, and being denounced as such to the authorities of the place, the board of health commissioned me to examine him. The unfortunate man was declared by the municipal physicians and myself to be affected with elephantiasis, and was consequently sent to the celebrated Lazaret of the island of Martires, in the lake.

I might mention similar cases. The same thing would happen with syphilis and contagion. Inheritance has a great influence in many cases of tubercular diathesis, for some members of families have been seen to be affected with pulmonary tubercles, others with elephantiasis, which in many of those affected with this complaint, above all in the atrophic form, often ends with pulmonary tubercular phthisis.

II.

The same causes cannot be assigned to partial or local elephantiasis, for it seems that the disease is only to be found in determined

localities, which would tend to prove that the causes are limited. It is impossible to extend one's self in a simple note, wishing only to record a few facts and observations that are not to be overlooked, as nothing ought to be despised that regards the sciences of observation and experimentation. In the locality of Maracaibo (the city, its environs, and adjacent villages) elephantiasis is very common; a proof of it being that the greatest part of those that are in the Lazaret come thence; and there are more than one hundred, besides those that pass unnoticed. Why does the same thing not happen with partial elephantiasis in the arms and legs? I have seen and treated several cases, but none from Maracaibo nor its adjacent villages, but from the Cordillera, the Distrito Sucre (Seccion Zulia), inhabited by colored people, and a case, if I mistake not, from Coro. I have seen partial elephantiasis of other organs in natives of Maracaibo (one single case), but none of the upper or lower limbs. The first and only case I saw was in the Hospital of Santa Ana, I being an externe, and one of my beloved teachers, Dr. Vicente Linarez, being physician of said hospital. The patient being a tall, lusty metis, having his left lower limb hypertrophied to such an extent that it resembled a big stump (pilon), an elephant leg. No treatment was successful, and the poor man left the hospital without my knowing whither he went, but of course feeling himself always as if he were bound to the earth by that enormous leg, that weighed perhaps as much as the rest of his body.

In 1867 a colored man from Sucre (then Gibraltar) made his appearance in the hospital under my charge, having his left upper limb affected with elephantiasis up to the third part of the arm. He could not support it, as he expressed himself, and begged for amputation as soon as possible, to get rid of that torment. I employed the iodides, *intus et extra*, arsenical preparations, compressive bandages, till I was able to prevail upon him to abandon the idea of having his limb amputated. He was a planter, always in the wet, but never had been affected with syphilis. I did not comply with the patient's wish, fearing that the operation would prove fatal. He then asked for his dismissal, which I granted. Several days after, I was invited by Dr. Francisco Suarez to go to the hospital under his direction to perform the amputation of an arm. At one o'clock P.M. I presented myself, with my assistants, internes of the hospital under my charge, Maniero and

Ramirez, and we three were surprised to meet with the same individual that had come to another hospital to demand the amputation I had refused. I frankly manifested my opinion to my friend and colleague; but he considered himself authorized to perform the operation, inasmuch as no remedy could free the desperate man from that burdensome arm. Declining for my part all responsibility, I performed the operation in the upper third, expecting to find there the tissues uninjured. I must say that the vessels were in perfectly good state, the ligatures were easily applied, the dressing according to the ordinary method employed at that time, and, though we all feared that the process of cicatrization would be unsuccessful, the healing was rapid and complete. The patient left the hospital and I lost sight of him.

About six or eight months after, the same person applied to the Hospital of Chiquinquira, where he was admitted. In the visit I met again with that unfortunate man, whose hopes had so soon vanished away, having then his left lower limb affected with elephantiasis. What had produced that terrible repullulation of the fatal disease? I do not know, but I noted down that fact, which I did not consider extraneous to the annals of science. I believe I have read something similar in an article of the Medical Dictionary in fifteen volumes, published from 1830 to 1835, and perhaps owing to that reminiscence I refused to accept the amputation. The general condition of the individual was bad: pallid, worn out, strengthless, destitute of digestive powers, in a diathetic state, having a lower limb enormously hypertrophied, with the characteristic aspect of elephantiasis; and lingering with a vespertine fever, died a few days after, not in the hospital, but in a village.

After I performed the amputation of the arm, and being convinced that the tissues of the stump were uninjured, excepting some connective tissue about the sheath that was hypertrophied, we proceeded to the dressing of the wound, and afterwards applied ourselves to the methodical inspection of the mutilated limb. In the first place we dissected the sheath, and found the artery and veins uninjured as far as we could follow them; but the lymphatic vessels were hypertrophied, soft to the touch and the scalpel, in all the length of the diseased limb, having a yellowish color, and in some parts rather pale gray. After the inspection, we concluded that the hypertrophied state called partial or local elephantiasis had its seat in the white vascular or lym-

phatic tissue. Is this hypertrophic disease a chronic lymphangitis? Is there any foreign element to the organism related to the places where this complaint is frequent (the Antilles)? Is it a parasitic disease that baffles all the therapeutical agents? I cannot say, and only wish to express my suspicions and doubts to scientific men; but whatever may be the extraneous cause, the anatomical tissue on which it acts is the tissue of the lymphatics.

How should we explain the metastasis of which I have spoken in this particular case? It is not probable that when the arm was amputated a germ of the disease should exist in the left lower limb; for, in the scrupulous inspection made over the body of the patient, none of the physicians observed the least thing that might point out the reappearance of the complaint in the left lower limb. This is certainly one of so many organic phenomena that are not to be scientifically explained. The mumps that descend to the pubic region, the phlegmon that appears sometimes in the calf of the leg in consequence of internal urethrotomy, the reappearance of some eruptions, as daily seen in medical practice, are positive phenomena not satisfactorily explained; but that fact has so far impressed my mind as to make me suspect that local elephantiasis may be allied to a general alteration of the liquids of the organism. In the second appearance of the disease, that man was not the same physiological subject; for in the first he was a healthy-looking man, excepting his burdensome arm, but in the second he had a sickly aspect and a deep alteration of the functions of nutrition. He was in a cachectic state. What had caused that change? I cannot tell, but some morbid element acted on that organism, infecting it, besides inducing hypertrophy of the left lower limb. So much darkness is to be dispelled only by gathering many similar facts and thoroughly studying them.

I entertained the conviction that this sickness was incurable, as the trial of the principal therapeutical agents, and even the amputation, had been altogether unsuccessful; but in 1873 I read in the *Bulletin de Thérapeutique* statistical information in regard to partial elephantiasis, in which the eminent observer proved that the ligation of the main artery in the diseased limb produced absolute amelioration, even the complete cure, according to several cases he had gathered.

The said paper mentioned about thirty successful cases of operation, and, on reading

those observations, I determined on trying the ligation in the first case that might present itself. The Casa de Beneficencia afforded it me,—a white, middle-aged man, from the Cordillera, who applied to that asylum on account of an enormous swelling of his left foot and leg. The physician of the hospital, Dr. Francisco Suarez, diagnosed partial elephantiasis, and was perfectly right in so doing, for the progress, the aspect, and all the circumstances of the case rendered this diagnosis evident, even to those destitute of experience. That patient was not only a subject of curiosity to the young students, internes and externes, but also a focus of infection to the hall where he had been placed, and a torment on account of the peculiar stench that came from him. The hypertrophy of the skin and of the subcutaneous tissue was such that the foot and leg were largely and deeply fissured, discharging a kind of yellowish serous pus, and diffusing an offensive and insupportable stench, that did not disappear even after applying the most powerful antiseptics. Dr. Suarez had submitted the case to the most energetic treatment, but without the slightest benefit. The physician had the kindness to put him under my care, and I proposed the ligation of the popliteal artery as the only resource, and both physician and patient accepted my opinion. Fixing the day for the operation, I performed it, assisted by several physicians and the internes and externes of the hospital, who now are all graduate and perhaps all remember well the case I describe, that must be registered in the annals of this asylum. The first case that was to be treated by ligation inspired natural curiosity. The disease had invaded all the leg and the popliteal region. The ligation could not be made according to the classical method, having to meet with abnormal difficulties, owing to the pathological state of the tissues. The skin was actually very thick, and a great portion of adipose tissue, hypertrophied and soft, formed a barrier before reaching the vessels that were imbedded in hypertrophied connective tissue, so that the incision had to be larger than ordinary, the artery being placed at a great depth. At last, having reached it, and isolating it, the needle was passed and the knot secured. The proper dressing was applied, the patient placed in the supine position, with the leg in a state of semiflexion.

The limb, of course, became rather cold, and I retired after prescribing the means of checking the effects of the sudden interrup-

tion of the circulation. On the following day I found nothing particular, only it seemed that the sero-purulent discharge produced by the fissures had diminished, as was also the case with the bad smell. After the lapse of about fifteen days the wound was healed without any inconvenience. By that time we were all convinced that the local complaint had evidently improved: the fissures disappeared, the skin looked thinner, and the color of the limb was more like the natural. The operation had favorably influenced that desperate case, therapeutically considered. Two months after the operation the patient walked freely about the hospital, and one day was dismissed, not by the physician, but by the director, his place being wanted for a patient that urgently required it. This was my first case of this class, and a very successful one indeed.

Some time afterwards I had in the hospital under my charge a case of elephantiasis of both legs, a white man from the Cordillera, 45 years of age, who was in a similar condition to the former patient, and, having proposed the operation, he submitted to it. I performed the ligation of the left popliteal artery in the presence of several physicians and students in service, not considering it prudent to proceed to both ligatures on the same day. This operation was perfectly well performed in the space of twenty minutes, having had the aid of Drs. Sanchez, Rincón, C. Oguendo, and others. The case was a very happy one in its results; and the patient seeing that in a short time his leg and foot tended to regain the normal form, asked for the second operation, which I ceded to Dr. Rincón, a skilful operator in the service of the hospital, who, having the aid of Dr. Oguendo, performed the ligation of the artery in the other limb, with the same successful result as the former. That man left the hospital nearly in perfect health, after having suffered a severe attack of yellow fever, which he recovered from.

These three cases of ligation of the popliteal to cure elephantiasis of the leg must be taken into consideration by those who practise in places where this disease is frequent or endemic. The ligature of the lingual has been recommended against the epithelioma of the tongue (its point). From the results I have obtained in the ligation of the popliteal, I am inclined to advise it before trying the amputation that nearly always brings but a transient cure, for soon after it the infected submaxillary ganglions announce the reap-

pearance of the terrible evil in another very important region.

CURE OF AN ANEURISM BY SUBCUTANEOUS INJECTIONS OF ALCOHOL.

In a case of extensively branching aneurism of the vessels of the occipital region, which had endured seventeen years, resisting all treatment, PLESSING injected alcohol with good results. Beginning with a thirty per cent. solution every two days, he soon increased the strength of the solution to seventy-five per cent., allowing a longer time to elapse between the injections.

In commencing the treatment, a dose of 20 minims was injected in four or six points of the tumor at one-half an inch from its border.

Pain, moderately severe, followed, but ceased in half an hour.

As the tumor became smaller and harder, the injections were made more nearly in the centre.

In two weeks' time a firm infiltration had formed about the tumor's margin, the skin was less tense, and the pulsations weaker.

In about a month, after the use of six ounces of fluid, the tumor was a firm mass, which showed pulsation in two points only: a necrosis of the skin occurred at these points, and erysipelas spread from these lesions. The infiltration of tissue partly disappeared; the pulsation did not return. In two months' time the patient was cured, and several months have elapsed without a recurrence. Pulsation and infiltration have alike disappeared.—*Deutsche Medicinal Zeitung*, November 25, 1886.

PEPTONE SUPPOSITORIES.

SAUTER prepares these suppositories with cacao butter, each containing twenty-five grains of peptone: they are mixed, and kept cold to prevent the fat from becoming rancid.

In cases where patients cannot be nourished in the normal manner, they serve an excellent purpose, fifteen grains of dried peptone equalling two and one-half drachms of meat in nutritive value.

Children may be given one suppository four times daily; grown persons, two three times daily. The suppository should be lubricated with olive oil, and the rectum previously cleansed by an enema.—*Pharmaceutische Post*, November 20, 1886.

DOSAGE.

IN the reading of a suggestive address upon the present state of therapeutics given by Dr. William Whitla, before the Ulster Medical Society, our attention was forcibly attracted by an account of his experience in one of the London hospitals. A brilliant clinical lecturer, speaking of the treatment of chorea, said, "From what I know and have seen of the pathology of chorea, I did not believe that arsenic could be of the slightest use to it; nevertheless, I determined to prove it, and I have demonstrated the fallacy which some men still cling to. I treated so many cases of chorea with teaspoonful doses of aqua camphora, and a similar series with arsenic, and the results were precisely similar. My large class of students have taken a deep interest in the experiments, and you can ask any of them do they believe in arsenic now." Possibly the distinguished physician knew positively very little about the pathology of chorea, certainly he failed to comprehend at all the therapeutics of the disease; for Dr. Whitla found that he was giving Fowler's solution in exceedingly small doses, whereas it is perfectly established that to have an

effect the arsenical solution in chorea must be administered in ascending doses until it produces puffiness about the eyes, albuminuria, or a marked gastro-intestinal disturbance, or, in other words, until it produces slight toxic effects. For the successful treatment of a disease the right remedy must not only be employed, but it must be given in the proper dose and in the right manner. Very frequently it is essential to produce distinct physiological effects of the drug; but in some cases a long-continued mild influence is necessary. Sometimes a single hard physiological blow will produce an effect not to be obtained by even a very continuous repetition of slighter blows, precisely as a rotten log may yield to a single powerful blow from the axe, but receive innumerable taps without splitting.

Although the subject has been so often written upon, and is so familiar as to be trite, yet possibly a few practical illustrations of the remarks just made may be of some service to some of our readers. At least in this part of the world strychnine is frequently prescribed in doses of a 40th to a 60th of a grain as a tonic during the convalescence of acute diseases, or during the nervous exhaustion which so frequently results from overstrain, or from the long-continued effect of hard work and cold weather during a long winter. In the amounts named the alkaloid is probably serviceable as a simple bitter in increasing the tone of the digestive organs, but that it has any general effect upon the vaso-motor system or upon the general nutrition is highly problematical. As an ordinary dose, $\frac{1}{10}$ of a grain of strychnine is not too large. We have given it three times a day in cases innumerable, and have never in more than one or two cases seen any evidences of its peculiar physiological action. When, as in protracted convalescence, or in extreme nervous exhaustion, or in the rapid loss of power of the spinal cord sometimes produced by metal-poisoning, a pronounced strychnic effect is desired, the doses should be rapidly increased until slight muscular stiffness, general unrest, or other evidences of toxic effect be manifested.

Some years ago it was our fortune to see a case in which after an acute illness the patient failed utterly to recover. Weeks went by, and there was no gain of strength or nutrition, although there was no disease present. Strychnine had been given in doses of $\frac{1}{10}$ of a grain three times a day. The nurse was ordered to give four granules a day, but thought that the physician meant to give four granules at a dose. The result after the third dose was a

decided but not serious attack of strychnine-poisoning, the secondary effect being that in two or three days the patient gained a great deal more in strength and general tone than he had previously in as many weeks, and in a very short time was practically well.

Not long ago we were called to a child five years old, suffering from violent sore throat and acute enlargement of the cervical glands, but without faucial exudation. We ordered two drops of tincture of belladonna to be given every two hours until our next visit unless some evidences of its action appeared. It so happened that the directions were plainly written upon paper, but the nurse gave 20 drops of the tincture until the child had taken 80 drops. A distinct poisoning resulted, though the symptoms were not very alarming and did not require treatment. The enlargement of the cervical glands and the sore throat disappeared in the night.

We sincerely trust that the lesson we are attempting to inculcate in this editorial will not be misunderstood. It is not that medicine should be given in indiscriminately large doses; it is that the physician should study the dose as carefully as the disease or selection of its remedy, and should adapt the dose, to the needs of the patient. We have seen a very minute dose exactly meet the requirements when a large dose of the same remedy would do harm. Thus, whilst in chorea arsenic must be given in overwhelming dose, in certain conditions of the mucous membranes, especially of the throat, good is achieved by giving very small amounts of the alterative for a length of time. There are certain persons whose throats become inflamed upon the least exposure to cold, the attacks yielding readily to treatment, but continually recurring. One or two drops of Fowler's solution given three times a day for four or five months will often so modify the constitution of the patient that the throat will remain well. The matter is one of considerable importance, since it is probably possible sometimes to stave off or prevent serious disease of the pulmonary mucous membrane which may end in a chronic consumption.

The excessive administration of medicines is a great evil. The physician should know just as well when to withhold as when to give. Boldness should be tempered by caution, and caution should be upheld by boldness.

VENESECTION.

WE have recently received the first volume of the "*Travaux du Laboratoire*," Université de Liège, under the editorship of Professor Fredericq. The volume contains researches of interest, most of them too purely physiological to be discussed in detail in our columns. There is, however, an elaborate study of the effect of the abstraction of blood which has a direct bearing upon practical therapeutics. Professor Fredericq finds that the effect of bleeding upon the cardiac pulsations is produced through the pneumogastric nerve, and varies in different animals according to the power of this nerve. In the dog and the pig the cardiac pulsations are accelerated and become uniform. In the ox and probably also in man the pulsations are simply accelerated. In the rabbit, in which the pneumogastric nerves have little power, the cardiac rhythm is not influenced. Contrary to opinions generally received, and based upon experiments made in the dog, in the rabbit the arterial pressure is greatly and enduringly lessened by a bleeding which does not exceed one per cent. of the body weight.

The effect of the bleeding upon the respiratory changes and upon calorification varies according to the state of the animal. In the rabbit during digestion bleeding produces marked lessening in the amount of oxygen consumed and the carbonic acid liberated, also in the amount of heat which is radiated from the animal when placed in a calorimeter. In the fasting rabbit the decrease in the consumption of oxygen is only momentary. In a little time the interstitial combustion rises again and frequently passes much beyond what it had been before bleeding. The animal put in the calorimeter gives off more heat than before the bleeding, although the rectal temperature is usually distinctly abated. It would seem, therefore, that bleeding gives rise to the dilatation of the cutaneous vessels.

Professor Fredericq conceives that his researches warrant the following conclusions:

First.—That it is only proper to employ bleeding to lessen the mass of blood when there is intense pulmonary, cerebral, or other congestion which demands immediate relief. That under these circumstances the bleeding simply is a means of putting aside an immediate danger.

Second.—That when, as in pulmonary œdema or in acute pneumonia, or in pleurisy, there is a sudden outpouring from the blood, bleeding

may do good by leading to the absorption of interstitial lymph.

Third.—Although in the dog the effects of bleeding upon the blood-vessels are so transitory, yet their permanency in the rabbit indicates that they may also in man be enduring, and therefore it is not irrational to withdraw blood when there is high vascular tension and imminent cerebral congestion or apoplexy.

Fourth.—That though the effect of bleeding upon the calorification might at first thought seem to indicate a field for usefulness in the treatment of febrile and inflammatory disorders, yet as bleeding seems to produce excessive destruction of the albuminous substances of the system, and therefore acts like fever, its employment for the lessening of fever is a very doubtful procedure.

STROPHANTHUS.

IN a previous issue we have already alluded to the cardiac stimulating powers claimed to be possessed by this drug. Unfortunately, the plant has been only obtained with great difficulty. There seems also to be considerable doubt as to what form of preparation is therapeutically most active, and we find various drug firms are using different parts of the plant for preparing the tincture, although Prof. Fraser has claimed that the seeds alone contain the active principle of this drug.

Dr. Fraser's formula for making this tincture is that one ounce of seeds, first deprived of their oil or fat by means of ether, in which the active principle is insoluble, is percolated by rectified spirits to produce eight fluidounces of tincture. Dr. Fraser has used tinctures of varied strength, but, finding the above too concentrated for convenient use, recommends one in which one part of the seeds alone without the hairs should be percolated with ten parts of rectified spirit, the dose of this tincture being 4 to 8 minims. He is especially emphatic in stating that the seeds and pods should not be used together, for, although the pods contain active principles, the relation of the tincture obtained from them and the tincture made from the seeds has not been determined.

Mr. W. Martindale, writing in the *Pharmaceutical Journal and Transactions* for November 20, 1886, states that he has examined tinctures prepared from the seeds, from the pericarp, and from the hairs, and, though he has found that all these parts contain the active principle, the tincture prepared from

the hairs is weakest, and that from the seeds is the strongest, in acting on the heart-muscle. They are also all of them powerful muscle-poisons, and, according to the statement of Mr. T. F. Bradford, this particularly applies to the pod tincture, but more experiments are needed to decide accurately their relative value. As the drug is an extremely expensive one, it is evident therefore that if other parts of this plant, in addition to the seeds, contain the active principle, they might for the sake of economy be used for preparing the active principle.

In this country Dr. C. L. Dana has extended our knowledge of the action of this plant through the report of a series of cases read before the Practitioners' Society of New York, on December 3, 1886 (*Medical Record*, December 18, 1886), in which he has used the drug. In one or two cases of Bright's disease in which Dr. Dana used this drug little or no striking benefit was observed as regards the cardiac irregularity and weakness, while in three cardiac cases progressive improvement occurred while the drug was being administered. In two cases marked improvement occurred after strophanthus was administered, while previously no special improvement was observed, three cardiac tonics having been already tried without avail in one case and two in the other.

Dr. A. A. Smith also stated that strophanthus had been used in the wards of Bellevue Hospital. In two cases of pulmonary oedema it was administered with good results. The first was a case of mitral systolic and double aortic lesion in which pulmonary oedema developed after unusual exertion. Five minims of the tincture were given every four hours, and the patient recovered. He also reported a case of pulmonary oedema occurring in pneumonia, and a case of emphysema, in which this drug appeared to produce excellent results.

Dr. Beverley Robinson at the same meeting read notes of twelve cases in which strophanthus was used with success, even in some instances after other cardiac tonics had failed to produce any result, though perhaps it is worthy of note that often the mere change from one cardiac tonic to another will increase the quantity of urine for a day or two, or more.

In this connection it is worthy of note that two enterprising English drug firms expect to become millionnaires at the expense of the public through the sale of this drug. We learn that these firms claim to have "cornered" the market in strophanthus, and have so advanced

its price as to make at present, in view of the uncertainty of its action, any ordering of the new heart-tonic in physicians' prescriptions entirely unwarranted. The present market price of the tincture of *strophanthus*—and it is to be noted that no definite strength is announced—is one dollar per ounce. Now, even if we admit that this tincture is made from the clear seeds and in the proportion first recommended by Prof. Fraser,—*i.e.*, one pound of seeds to eight pints of spirit,—that would bring the price of the seeds to one hundred and twenty-eight dollars per pound. We further learn that the English firms which are thus attempting to fleece the general public are offering the clear seed at one hundred and sixty shillings (forty dollars) per pound; and recollecting that the manufacturers of the tincture do not state that this tincture is made from the seeds alone, and that Dr. Fraser has more recently recommended a much more dilute tincture, it is evident that the profit made in this transaction must be simply enormous, provided the medical profession can be gulled into playing into the hands of such extortioners.

It is highly probable that this drug may prove to be a valuable adjuvant to our other means of treating a weak heart; but neither we nor our patients are compelled to rely on it alone, and until the manufacturing druggists learn that the medical profession cannot be played as puppets to fill their pockets, *Strophanthus Hispidus* should be let severely alone.

PILOCARPINE AS A GALACTAGOGUE.

TO a philosophical lover of his race few things are more disheartening or more saddening than a puling, whining, emaciated shadow of a baby dragging a fraudulent food from a no less fraudulent teat encasing the yawning mouth of the flinty bottle. Cheated in the very beginning of his life, the unfortunate being draws in, but not with his mother's milk, his first lessons of fraud. This disheartening spectacle is almost universal among the upper classes of Americans. In the race for civilization and culture the lacteal glands seem to have been left entirely behind. Any one, therefore, who would discover a medicinal or other method of bringing about an Eve-like development to our American women would confer a great boon upon the rising humanity, though he might incur the anathemas of the numerous manufacturers who batten upon the sufferings of

the young and the deficiencies of the old. Castor oil leaves, faradization, ale, milk, and the various remedial measures employed by the laity and the profession to remedy the great and growing evil have in the past amounted to nothing. We therefore, with not altogether untempered hopefulness, call the attention of our readers to the investigations of M. Chéron, who has studied the action of pilocarpine upon the mammary glands, and believes that he has found in it a specific. The treatment has been practised by him in nine cases with satisfactory results in all but one. Five centigrammes of the nitrate of pilocarpine were hypodermically injected as soon as the milk became scanty, whether this took place suddenly or by degrees. The injection was repeated every day. Under its influence the skin of the face and, afterwards, that of the body became hot for a few moments, but there was seldom any moisture. It is essential to success not to produce diaphoresis. If the scantiness of secretion has existed for some time, ten or twelve injections are required; on the other hand, if it has come on suddenly, two or three will suffice. The treatment had no ill effect either on the nurse or the nursling.

A NEW LOCAL ANÆSTHETIC.

IT is well known in Southern Australia that a great many sheep and cattle are annually killed by eating *Euphorbia Drummondii*, which is very poisonous, according to the quantity of milky juice which it contains. It appears from the statement of Dr. Schomborgh that sheep, bullocks, and horses die in from twenty-four hours to seven days after eating it. They present paralysis of the extremities, hanging of the head as if tipsy, while the body does not seem to be impaired. At first the weed is avoided, and taken only on account of extreme hunger, but afterwards it is sought after and eaten with great avidity.

Dr. John Reid, of Germein, announces in the *Australasian Medical Gazette*, No. 61, 1886, the discovery of an anæsthetic alkaloid in this plant, which he terms drumine. The method which he employs for the isolation of this alkaloid is to make a tincture, which, after standing for a few days, is evaporated to get rid of the spirit, ammonia added in excess, and the solution filtered. The residue, after the ammoniacal odor has disappeared, is dissolved in diluted hydrochloric acid, and the filtrate is filtered through animal charcoal to

destroy the abundant coloring-matter. The filtrate is evaporated slowly, and leaves the alkaloid. This alkaloid deposits from solutions in acicular and stellate crystals with little taste, freely soluble in chloroform and water. The crystals deposited from the hydrochloric acid solution and filtered through animal charcoal are circular or boat-shaped at the circumference, and stellate, or perhaps more correctly, disks, as if formed of concentric circles, with radiating fissures. They are colorless, and under a high power of the microscope the acicular crystals are in some cases rhomboid in shape. Dr. Reid thinks that perhaps this difference in shape, and the different degrees of solubility of these different-shaped crystals in chloroform, would perhaps indicate that two alkaloids are present, but his researches have not yet enabled him to speak positively on this point.

Experimenting on cats, Dr. Reid found that on placing a few drops of a four per cent. watery solution of this alkaloid in one of the eyes, in a few moments it was tolerant of contact with the finger, while the pupil was not appreciably dilated. In another instance he injected 3 grains subcutaneously in the back, and, apart from anæsthesia, with the production of no apparent effect. The following day he states that he gave a large dose to the same animal, but does not name the quantity, and in a few moments the legs were completely paralyzed, while breathing was slow and performed with difficulty. As the animal was apparently dying, strychnine was injected, and produced only a few fibrillary twitchings of the face-muscles, but no general convulsion, and death soon followed. Dr. Reid also experimented with this drug upon himself, trying it upon his tongue, nostrils, and hand, and found very marked anæsthesia in all cases, even the sense of taste and the bitterness of quinine being abolished on the side of the tongue to which it was applied. Taken internally, he found that small doses, although he does not say in what quantities it was administered, produced no constitutional effects. In a case of sciatica in an old man, a subcutaneous injection of 4 minims of a four per cent. solution relieved the pain. He also employed it in a case of catarrhal jaundice, relieving the pain and tenderness in the stomach, and in neuralgic tic it has produced successful results by dropping it in the eye.

It is to be regretted that Dr. Reid's experiments are so crude, and show such entire ignorance of the commonest methods of pharmacological investigation, as to give no reliable

conception as to what is the action of this alkaloid. It is to be hoped that the plant will be subjected to a renewed analysis that Dr. Reid's statements may be confirmed or disproved, and that the alkaloid, if such be present, be subjected to thorough physiological and clinical examination.

WE welcome to our exchange table the new journal of *Laryngology and Rhinology*, which is to be edited by Drs. Morell Mackenzie and B. Norris Wolfenden, and published monthly by the Churchills, of London, and P. Blakiston, Son & Co., of Philadelphia. We should suppose that the journal would be an absolute necessity to all those who treat diseases of the throat and nose. It is chiefly composed of abstracts from the world's recent literature, and reports of the transactions of French, German, English, and American societies. To us it appears to thoroughly represent the current thought on the subject.

Reports on Therapeutic Progress.

THE ANTISEPTIC TREATMENT OF SUMMER DIARRHŒA.

At the annual meeting of the New York Academy of Medicine, held January 6, 1887, Dr. L. EMMETT HOLT read a paper on the "Antiseptic Treatment of Summer Diarrhœa" (*Medical Record*, January 15, 1887). The speaker stated that he did not undervalue other methods of treatment than the use of drugs, such as careful feeding, change of air, etc., but the object of the paper was to discuss what additional measures were useful.

All the causes of summer diarrhœa—excessive heat, improper or artificial feeding, and bad hygienic surroundings—united to produce a dyspeptic condition, which was really at the bottom of nearly all of these cases. The age showed it could not be heat alone, for the disease was not frequent at the most tender age,—under six months. Of 431 cases, only twelve per cent. were under six months, while fifty-nine per cent. were between six months and two years. The explanation was that under six months most of the children were fed at the breast. Improper and artificial feeding was quite as important as heat, as Hope had found in 591 fatal cases that only 28 had no food but the breast.

Heat depressed vital energy, increased de-

composition in the streets and sewers, and thus vitiated the atmosphere; but, most of all, it produced in the food given to young children putrefactive changes before it was taken into the stomach.

This was especially likely to occur with milk. One instance was cited of every one of twenty-three healthy children being taken in one day with diarrhoea from bad milk.

Closely related to this subject were the poisons produced from food, or ptomaines. Brunton had stated that most of the alkaloids produced from the decomposition of albumen caused diarrhoea. It was believed that many of the nervous symptoms in summer diarrhoea had their explanation in the effects of these alkaloids. This was true especially where the discharges were abruptly arrested, either spontaneously or by opium. They were to be looked upon as a form of toxæmia.

The inflammatory changes found in the intestine were to be looked upon as a consequence of the diarrhoea rather than the cause of it. The most marked lesions were always found in the cæcum and sigmoid flexure, just where the irritating substances were longest detained in their passage.

Immense numbers of bacteria were found in the discharges, but no sufficient evidence had yet been adduced to establish the existence of a special microbe as a causative agent.

The indications for treatment were four: 1. To clear out the bowels. 2. To stop decomposition. 3. To restore healthy action in the alimentary tract. 4. To treat the consequential lesions.

It was proper to begin with a cathartic in all cases unless the stomach was very irritable. Castor oil was by far the best. If much vomiting were present, a copious injection of water, enough to wash out the colon, should be given.

Many mild cases could be cured by the oil alone, provided suitable dietetic regulations afterwards could be carried out. In severe ones it gave only temporary benefit.

For the second and third indications an antiseptic should be given and the diet carefully regulated. The best antiseptics were sodium salicylate and naphthalin. The former should be given in doses of 1 to 3 grains, according to the age of the child, every two hours, and the latter in about double the dose.

If vomiting were present, all food should be stopped for from twelve to twenty-four hours, and thirst quenched by thin barley-

gruel or mineral-waters,—cold, and in small quantities.

Unless the child were upon the breast, in which case it should, of course, be kept there, it was better to *withhold milk entirely*. Wine-
whey, animal broths, expressed beef-juice, or even raw beef, could be used, and were usually sufficient.

To meet the fourth indication—*i.e.*, to treat the lesions—astringents by the mouth were useless, with the possible exception of bismuth. The diet should be as carefully looked to in chronic cases as in acute. The antiseptic should be continued, to check fermentation and decomposition in the intestine, and the large intestine should be washed out once a day with pure water or a weak antiseptic or astringent solution.

Attention was called to the fact that, except opium, nearly all the drugs which had held their place in the treatment of this disease were antiseptics of more or less power. Bismuth, calomel, the mineral acids, iron and silver salts were cited. Pure antiseptics had been used in the treatment of diarrhoeal diseases since 1846. Creasote was first employed, and with great success both in England and in this country. Ten or fifteen years ago salicin was largely used, especially in the South, with uniformly good results, particularly in chronic cases. The use of salicylic acid and its salts, the bichloride of mercury, and naphthalin was also referred to. The last was of latest introduction, and seemed likely to prove of very great value, perhaps the most valuable of all.

Notwithstanding the successful results obtained by antiseptics, the great majority of the text-books still advocated the old plan of the use of opium and astringents as fifty years ago. An inquiry into the public practice of this city showed that in fourteen institutions and dispensaries, where it was estimated that twenty-five thousand children were treated yearly for diarrhoeal diseases, the main reliance was still upon opium, bismuth, chalk mixture, and castor oil.

The speaker had tabulated 300 cases of his own treated by such remedies. Of these, 50 per cent. were cured; 27 per cent. improved; 18 per cent. unimproved; and 7 per cent. died. During the past year he had treated 81 similar cases by an initial dose of castor oil, followed by salicylate of sodium, these being the only drugs used. Of these, 84 per cent. were cured; 7 per cent. improved; 7 per cent. unimproved; 1.2 per cent. died. Forty-four cases were treated by naphthalin,

usually preceded by the oil. Of these, 67 per cent. were cured; 15 per cent. improved; 13 per cent. unimproved; and 2 per cent. died. Resorcin was used in a similar manner in 27 cases. Of these, 55 per cent. were cured; 22 per cent. improved; 22 per cent. unimproved; and none died.

The duration of the disease in these cases before treatment was about the same in each class. The duration of treatment in the cured cases was much shorter by sodium salicylate than by the use of opium, astringents, etc. In cases of long standing the very great superiority of the salicylate and naphthalin was clearly shown. Resorcin was much inferior to the drugs just mentioned.

The following conclusions were drawn from the paper:

First.—Summer diarrhoea is not to be regarded as a disease depending upon a single morbid agent.

Second.—The remote causes are many,—heat, improper and artificial feeding, bad hygiene, etc.

Third.—The immediate cause is the putrefactive changes which take place in the stomach and bowels in food not digested, which changes often are begun outside the body.

Fourth.—These products may act as systemic poisons, or the particles may cause local irritation and inflammation of the intestine.

Fifth.—The routine use of opium and astringents is not only useless, but, especially at the outset, may do positive harm; since, by checking peristalsis, opium stops elimination and increases decomposition.

Sixth.—Evacuants are to be considered an essential part of the antiseptic treatment.

Seventh.—The salts of salicylic acid and naphthalin are the antiseptics which, thus far, seem to be best adapted to the treatment of diarrhoeal diseases.

DR. R. W. WILCOX spoke especially with reference to the use of naphthalin in diarrhoea in adults. Since reading Rossbach's paper in the *Berliner Klinische Wochenschrift*, in November, 1884, he had used naphthalin in thirty-two cases, nearly all being in adults. He had come to feel as much confidence in the use of this drug, under certain circumstances, as in the use of mercury or the iodides in syphilis or of quinine in intermittent fever. As mercury and quinine may fail to accomplish their work if used without observance of a few well-known precautions, so naphthalin may fail if improperly employed. The most frequent cause of failure has been

the use of too small quantities, less than 60 grains daily being a needless waste of a very good medicine. He had given up to 120 grains during the twenty-four hours in divided doses, usually in starch capsules with a small quantity of oil of bergamot to conceal the somewhat unpleasant odor. If the impurities of the drug are removed by washing with alcohol, no such untoward effects as have been occasionally reported in the journals will occur. Frequently during its administration the urine will assume a smoky color, resembling that of acute nephritis, but a careful examination will fail to detect either albumen or casts.

In chronic diarrhoeas he had used naphthalin as the only drug in twenty-one cases. Nearly all degrees and varieties had been represented; some could be traced back to an acute process, others were the result of improper food or followed debilitating diseases.

He related one case: James D., messenger, 18 years of age, came to him, complaining of a diarrhoea of over two years' duration. Its commencement was in the second summer previous to his first visit. The assigned cause was overindulgence in unripe or spoiled fruit. The trouble had continued through the following winter, with intervals of cessation, and had been aggravated the following summer. Since summer his loss of flesh, previously considerable, had increased, his tongue was heavily coated, the appetite poor; his discharges were five to six daily, unformed, varying much in amount, sometimes watery, very foul-smelling, much gas, no tenesmus, no blood; pain at times, but no fever. Although he was in a deplorable condition, and so long as his work remained severe and his food unsuitable recovery seemed impossible, by the use of 60 grains of naphthalin daily the number of movements were reduced, within a week, to two daily, and, for the first time, became formed and devoid of odor. About six months afterwards he reported that after three weeks he had discontinued his medicine, having had no further necessity for using it.

In *chronic dysentery* he had used naphthalin in seven cases, with excellent results. The most interesting case was that of James C., 66 years of age, who contracted dysentery while serving in the Federal army in 1862-64. He had never been free from the disease except for a few weeks at intervals. He could remember no day during which he had not had more than one passage. He was ema-

ciated, with sallow, dirty skin, marked tenesmus, abdomen painful on pressure, red tongue, pulse very feeble, no appetite. His stools averaged seven movements daily,—slimy, blood-stained, of extremely foul odor. This man had 90 grains of naphthalin daily, and at the end of the month he would have hardly been recognized as the same man. Four months after he reported himself so much improved that he considered himself a well man.

His experience in the diarrhoea of *typhoid fever* had been limited to two cases: Charles B., 25 years of age, and John F., 16 years of age, both of whom he saw for the first time in the third week, the diagnosis being thoroughly established. In both there was commencing tympanites; diarrhoea, to the extent of six to ten passages in the twenty-four hours. Naphthalin was administered up to 60 and 90 grains in the day, with the result of "stiffening up" the motions and reducing them to two daily. The odor of the stools, in both cases, was lost. In fact, he felt so confident that the intestinal canal and, consequently, the fæces were disinfected that he did not take any other precautions. He also directed attention to the antipyretic effect of this drug. In general, the use of antipyretics in typhoid fever he considers unsafe; but if the practitioner was thoroughly imbued with the idea that he must use an antipyretic, let him use naphthalin, which reduces temperature, indirectly, by disinfection of the intestine. In point of safety it compared favorably with such drugs as antifebrin, thallin, antipyrin, etc. Whether typhoid fever had ever been aborted by this or any other drug he did not pretend to say; but if it could be accomplished, in his opinion, naphthalin, by its vigorous action upon the contents of the alimentary canal, should tend to that result.

Of the use of naphthalin in acute intestinal catarrhs, and in the diarrhoeas of children, he had had no experience. In the diarrhoea of chronic tuberculosis he had had no opportunities for experiment. In all his cases of diarrhoea evidences of tuberculosis in other organs were sought for, but were not found. He would emphasize the claims of naphthalin as *the* drug to use in all cases in which it was necessary to disinfect the alimentary canal, as in typhoid fever, intestinal catarrhs, and dysentery, because it seems to be, of all the drugs at our disposal, the most certain, and at the same time the one most free from danger.

THE MEDICATION OF PHTHISIS.

In a recent number of the *Progrès Médical* the editor discusses the changes in the treatment of phthisis which modern pathological researches would indicate. Recent suggestions in antibacilli treatment are the inhalation of hydrofluoric acid and the rectal injection of sulphurous gas.

We are able, however, to hope for very little from these methods.

The means for combating tuberculosis which seems most worthy of serious attention is the use of iodoform.

This substance has been tested by injection in cold abscesses, by inunction in tubercular meningitis, and internally given in enlarged glands and pulmonary tuberculosis. The purity in which iodoform is now made, our better knowledge of its solubility, and its poisonous properties, enable us to use it as a most important agent in the extirpation of a local tuberculosis before the organism can become affected; it has thus an important part in preventive and hygienic medication.

We must agree with Jaccoud in placing the administration of nutritious elements as still our most important duty to the phthisical patient. Cod-liver oil, to the extent of 4 ounces daily, is of the greatest benefit, and especially those oils which contain iodine and phosphorus in greatest amount.

AN IMPROVED METHOD FOR COM- PRESSING AIR.

DR. E. L. OATMAN, of Nyack, N. Y., sends to the *N. Y. Medical Record* (December 25, 1886) an account of a simple and apparently very effective method of compressing air for use in atomizing fluids. In the cellar or basement a common galvanized iron range-boiler is placed, and connected by two pipes, entering it below, with the main water-supply and with the drain. At the upper end a tube is attached, which passes up to the physician's office. All the pipes are fitted with stop-cocks. To charge the reservoir, this air-tube and the discharge-pipe are closed, while the supply-pipe is opened. The water now rushes in, and places the contained air under a high pressure. When the water ceases to flow, the supply-pipe should be closed. The compressed air may now be used when required by opening the air-pipe, the stop-cock of which is placed in the office. When the pressure is exhausted, the reservoir may be emptied by opening both the air-tube and the discharge-

pipe, and the air may then be again compressed as before, by closing the latter pipes and opening the supply-pipe. The discharge-pipe should be of large calibre, say two inches, so that the apparatus may be quickly emptied. The arrangement would be improved, Dr. Oatman writes, by using two connecting reservoirs, allowing the water to enter only the first, which should be the larger of the two, thus compressing the air in the second, where it can be kept ready for use. The water may now be discharged from the first, for which purpose it should be provided with a second air-tube, leaving it ready for instant use when the pressure is exhausted in the second reservoir. All the cocks governing the tubes of the apparatus may be placed in the office, if desired. Ten dollars will cover the entire cost of the apparatus.

RECENT RESEARCHES IN DIURETICS.

To what extent the Malpighian corpuscles and the renal tubules respectively take part in the secretion of urine is not yet accurately known, although the researches of Heidenhain, Nussbaum, and others have added much to our knowledge. It seems likely that an investigation into the mode of action of diuretics will throw great light on the question, because a diuretic drug may act either on the Malpighian corpuscles, increasing the flow of urinary water, or on the renal tubules, increasing the amount of urinary solids, or on both structures. The great difficulty, however, in experiments on the kidney in living animals, is that of estimating how much of the effect produced by a drug is due to changes in the circulation, or in the nervous system, which has an influence on the secretory activity of the kidney, as well as on the blood-vessels. MUNK has, in his recent experiments, eliminated these factors by investigating the action of diuretic drugs on an excised kidney. The organ, after excision, was nourished, under a pressure of one hundred to one hundred and ninety millimetres of mercury, by a stream of blood and salt solution through the renal artery. The drug was added to the liquid, and its effect noted by the amount and quality of the urine, collected through a canula placed in the ureter. Before the addition of any drug, it was found that the amount of urine secreted in an hour varied from four to twenty-four cubic centimetres; that this was a true secretion, and not a simple diffusion, was shown by the fact that it contained a greater proportion of saline constituents than

the circulating fluid. The addition of chloride of sodium, nitrate of sodium or potassium, caffeine, dextrose, cane-sugar, or glycerin to the circulating fluid, increased the secretion of urine three to fifteen times, the pressure remaining the same; while in the case of nitrate of potassium and of caffeine, there was an increased rapidity of flow of the circulating fluid. Diuresis of this nature and under such conditions could only result, according to Munk, from a stimulation of the secretory cells of the kidney by the drug, a conclusion which, as regards caffeine, had already been arrived at by Von Schroeder. An interesting result obtained by Munk was the appearance of hippuric acid in the secretion from the kidney, when benzoate of sodium and glycol were added to the fluid circulating through the vessels of the kidney. As is well known, benzoic acid given to any animal appears as hippuric acid in the urine; and this result has been supposed to be due to the action of the intact blood-corpuscles. But, in Munk's experiment, these were absent; hence he concludes that the transformation is probably brought about by the oxygen which is combined with the hæmoglobin.—*British Med. Journal*, December 11, 1886.

ELIMINATION OF POISONS.

A study of the means by which nature rids the economy of what is harmful has been made by SANQUIRICO, of Siena, and his experiments and conclusions are as follows:

He finds that the vessels of the body, without undergoing extensive structural alteration, can by exosmosis rid themselves of fluid to an amount eight per cent. of the body weight of the subject of the experiment.

Through the injection of neutral fluids a great increase in the vascular tension is effected, which is relieved by elimination through the kidneys.

With reference to this fact, the author, in 1885, made experiments with alcohol and strychnine, and continued his researches in the use of chloral and aconitine with results favorable to the method employed, which is as follows:

The minimal fatal dose of a given poison was selected, and found to be in a certain relation to the body weight.

Immediately upon the injection of the poison a solution of sodium chloride, .75 per cent. in strength, was injected into the subcutaneous tissues of the neck, in quantities

being eight per cent. of the body weight of the animal.

In the case of those poisons whose effect is not instantaneous, the injection of saline solution was made on the first appearance of toxic symptoms; in other poisons the injection was made at once.

The result of the use of salines was a diuresis varying in the promptness of its appearance and in its amount.

Those animals in which diuresis was limited at first and then increased generally recovered, while those in which diuresis was not established perished; the poison used was found in the urine of those which died and also those which recovered.

The author succeeded in rescuing animals poisoned by alcohol, strychnine, chloral, and aconitine; with morphine, curare, and hypnone the method of elimination failed, although ten per cent. in quantity of the body weight of the animal was used in the saline injection. With aconitine diuresis was not always established, and when it failed the animal died in convulsions.—*Centralblatt für die Medicinischen Wissenschaften*, December 18, 1886.

ACETANILIDE—A NEW APYRETIC.

A substance known to chemists who work with dyes by the name of acetanilide, which is produced by the action of heat on acetate of aniline, and is contained in rosaniline made with acetic acid and iron, has recently been found by two German observers, Drs. CAHN and HEPP, working in Professor Kussmaul's clinic, to possess powerful febrifuge or apyretic properties. They have given it the trivial name "antifebrin." It appears to have, weight for weight, about four times the power of lowering the temperature of fever-patients that antipyrin has. The doses given varied from 0.25 gramme to 1 gramme, as much as 2 grammes ($\frac{1}{2}$ drachm) being given during the twenty-four hours. In every case in which Drs. Cahn and Hepp gave the drug, it produced more or less reduction of temperature; sometimes the thermometer registered a normal temperature for some hours together, and in these cases the appetite often returned. The action of the antifebrin was accompanied by a certain amount of perspiration and with some redness of the skin, sometimes also by thirst and an increase in the urinary secretion. Occasionally a dark tint was observed in the skin of the feet and hands, but no serious symptom was observed in any of the twenty-four cases in which it

was given. The price of the acetanilide is not high, being about a shilling an ounce. It can be administered conveniently in wine.—*British Medical Journal*, December 4, 1886.

INTESTINAL IRRIGATION IN CATARRHAL ICTERUS IN CHILDREN.

MONTI, in his clinic for children's diseases, has extensively employed the treatment of jaundice from icterus catarrhalis by cold-water enemata.

This treatment is well borne by children over three years old, and the water is used at a temperature varying from 50° to 60° F., and in quantities from one to two quarts. The presence of diarrhoea is not a contraindication. In the larger number of cases four or five irrigations were sufficient to effect a cure; in one case only were eleven needed. The dyspeptic symptoms, clay-colored stools, and engorgement of the liver were promptly relieved by two or three irrigations. Löwen-thal, of Berlin, reports good results from this method in forty-one cases.—*Medicinisches Chirurgische Rundschau*, December 15, 1886.

THALLIN IN TYPHOID FEVER.

The introduction of such drugs as kairin, antipyrin, and antifebrin has somewhat diverted attention from a very powerful antipyretic agent,—viz., thallin. PROF. EHRLICH lately presented to the Clinical Society of Berlin the results of some researches he has been making with this last-named agent, especially in the treatment of typhoid fever (*Münch. Med. Woch.*, No. 47). From experiment, he had found that after administering the drug to animals it was not retained in the nerve-centres, but mostly in the fatty tissue of the body. He also found that there was a marked difference in toxic action, according as to whether it was administered by the mouth or subcutaneously, the greater inertness of its effect in the former case being attributable to the hindrance to absorption from the presence of intestinal contents. The lesions induced by a toxic dose comprised fatty degeneration of the kidneys, necrosis of the salivary glands and pancreas, and hemorrhagic infarcts in the renal pyramids. The chief action of thallin is antipyretic, but it is capable also of moderating inflammation. As regards typhoid fever, it was administered by Ehrlich in two different ways. The first plan consisted in commencing with doses of 0.06

gramme every hour, and reducing the dose to the minimum required to give any effect. The other plan was to commence with a minimum dose, and increase it until an effect was produced, and then to continue the prescription at the dose thus attained. The action of thallin is especially noticeable in its effect on the sensorium and general condition of the patient, who presents the appearance of convalescence, whilst the splenic swelling and roseola are still present; and if the drug be discontinued the temperature will rise again. It is not therefore surprising to learn that, whereas of twenty-eight cases treated by bathing the average stay in hospital was thirty-seven days, of seven cases treated by thallin (minimum doses) the duration of treatment was forty-seven days, and cases on a scale of progressive doses thirty-eight days. However, Professor Ehrlich claims advantages for the drug in the absolute control it exerts over the pyrexia, and the sense of well-being enjoyed by the patient. There were no intestinal hemorrhages in these cases, and no instance of perforation. The kidneys were not affected, but sequelæ in the form of hyperæmia and œdematous swellings seemed due to the use of the drug. It was not thought that thallin had any specific action against the typhoid bacillus, but it did seem to limit the degree of intestinal ulceration. Professor Ehrlich considers it to be on a level with the bath treatment. Dr. Fränkel pointed out that if the statement were correct that thallin is not found in the nerve-centres its action in reducing temperature was rather inexplicable. He had exhibited it in increasing doses, but could not say that the patients experienced any special benefit attributable to the diminished fever. Dr. Guttman had not been favorably impressed by its use, and had noted the production of rigors.—*The Lancet*, December 25, 1886.

THE EFFECT AND ELIMINATION OF BORAX AND BORACIC ACID.

The extensive use of borax and its compounds as antiseptics has given especial interest to the question of the poisonous effects and mode of elimination of this drug. Johnson, of Stockholm, has made clinical studies upon this subject by introducing borax and its compounds into the stomachs of patients in the Caroline Institute, and has tested for borax by the curcuma test, which, in proportions of 1 to 2000, gave well-marked reaction, and also by the spectro-electric tube of Vigier,

which detects only the proportion of 1 to 1000. In twelve cases in which the dosage ranged from 20 grains to 50 grains daily in irregular doses, after the largest doses had been taken, three exhibited signs of intoxication, headache, vomiting, malaise; in one case, after the use of borax for ten days, a slight acceleration in the pulse-rate was observed, accompanied by increase of temperature, loss of appetite, headache, redness of the fauces, and bronchial catarrh, and finally by a well-marked papular erythema upon the thighs and joints. The urine commonly gave a reaction for borax ten minutes after the dose was taken: it was not found in two days after the drug had been used by inunction. In other cases it persisted in the urine six, eight, and fourteen days after the patient took it. Boracic acid had a distinctly diuretic effect: albumen disappeared from the morning urine in some cases where albuminuria existed; when the greatest diuresis was produced, the drug itself disappeared from the urine. Borax was found in the perspiration; in small amounts in saliva; irregularly in fæces, often after several days' ingestion, which the author thought due to its presence in the bile. Twice borax was found in ascitic fluid.

It is interesting to observe that after foot-baths containing boracic acid borax was found in the urine, and also after the application of vaseline containing boracic acid to an ulcer it was present for two days after its use. Its presence in the organism after its use with hot-water applications is probably owing in part to the influence of the steam which is present. Johnson's observations do not tend to show the danger of the use of borax and its compounds, but to call attention to the fact that after its use in the stomach, intestine, bladder, and pleural cavities ill effects have followed a five per cent. solution, and the observer advises that after the use of solutions of a strength of two per cent. or over, care be taken that no great amount of the fluid remain in the body, and that after-injections of water or neutral carbonates be made as a prophylactic measure.—*Medicinisch-Chirurgische Rundschau*, December 15, 1886.

CHLORIDE OF METHYL IN THE TREATMENT OF NEURALGIC AFFECTIONS.

From an experimental paper with the above title, published in the *Kansas City Medical Index* (December, 1886), DR. DUDLEY TAIT draws the following conclusions:

1. Chloride of methyl spray may be used

with great advantage in all neuralgic affections; its sole indication is pain.

2. It can be successfully resorted to in view of eradicating pain in the course of various pulmonary affections, in acute and chronic rheumatism, and also in affections similar to writer's cramp, etc.

3. In trifacial neuralgia, precaution is of absolute necessity, but does not constitute a counter-indication.

4. One application often suffices; however, two and exceptionally several applications are necessary.

5. The majority of neuralgic affections are definitely cured by this treatment; success has sometimes been obtained in neuralgias symptomatic of Pott's disease, pelvic tumors, etc.

6. The slight and *transient* pigmentation that sometimes follows this treatment is of no importance; it disappears in the space of two weeks.

7. Experiments seem to indicate that the analgesic properties of chloride of methyl are due to its action on the superficial terminal expansions of the nerves of the skin.

TREATMENT OF SYPHILIS BY SUBCUTANEOUS INJECTIONS OF CALOMEL.

BALZER has treated syphilis by the above method, employing the following combination:

Calomel, gr. viii;
Oil of vaseline, ʒiiss .

The first case in which this treatment was employed was that of a patient who had roséola and mucous patches upon the vulvæ, which had resisted all other modes of treatment. The first injection made contained $\frac{1}{2}$ of a grain of calomel, the second injection contained 1 grain.

A vigorous inflammation occurred at the place of injection, but without suppuration. Eight days after hypodermic medication began, the unpleasant symptoms which had so long annoyed the patient disappeared.

The author has treated five other patients similarly, and with excellent results.

Two hours after injection traces of calomel are found in the urine.

Scarenzio and Smirnoff have treated secondary syphilis with 8 grains of calomel in four doses, and at intervals of twenty days. They claim good results, without returns of the disease.

The use of the oil of vaseline as a vehicle greatly diminishes the tendency to form abscesses after hypodermic injection.—*La Presse Médicale*, December 5, 1886.

THE INFLUENCE OF COCAINE ON THE ACTION OF ESERINE ON THE EYE.

It was remarked by Wecker in the *Annales d'Oculistique* (1884, t. xcii. p. 218) that the action of eserine on a cocainized eye is greater than when no cocaine had been used. This difference he attempted to explain by suggesting that the slight cocaine-anæsthesia of the iris and ciliary body may cause a somewhat similar effect on the pupil to that of eserine. DR. E. L. TUREVICH, however, who has recently published a "preliminary communication" on this subject in the *Vratch*, points out that the action of cocaine by itself on the pupil and accommodation is exactly the reverse of that due to eserine, cocaine dilating the pupil and paralyzing the accommodation, while eserine contracts the pupil and causes spasm of the accommodation; besides, it has been conclusively shown that a combination of atropine and cocaine produces a more powerful dilating effect on the pupil than atropine alone; and Ad. Weber has even given the equivalents of eserine and pilocarpine as antagonists of cocaine, these being 1 to 25-30 in the case of eserine, and 1 to 4 in the case of pilocarpine. The fact of eserine acting more powerfully on a cocainized eye is therefore paradoxical, and by no means easy to explain. How, writes Dr. Turevich, can the anæsthesia of the ciliary body, even if cocaine does produce such an effect, which is extremely doubtful, favor the action of eserine, as Wecker suggested? We should *a priori* expect that the contraction of the pupil by eserine in a cocainized eye would be, if anything, less than in an ordinary eye; and indeed it was shown by Weber that when a drop of a two per cent. solution of eserine was combined with 25 to 30 drops of a similar solution of cocaine, its effect on the pupil was entirely masked. In the hope of clearing up the paradox, Dr. Turevich undertook a series of observations on the paralyzing effects of eserine and pilocarpine on his own eyes and on those of others, both with and without the previous instillation of cocaine. The course of the accommodation-spasm was observed by measuring the refractive power of the eye every five minutes from the application of the eserine or pilo-

carpine to the time when the effects had passed off. Fifteen comparative observations were made, which completely confirmed Wecker's statement as to the greater effect of eserine on a cocainized eye, showing also that the same is true of pilocarpine. The explanation suggested of the apparently opposite action of cocaine when applied previously to the eserine and when combined with it is that when anæsthesia of the conjunctival sac is present,—first, the surface absorbs more of the eserine than when the eye is as sensitive as usual, the introduction of a foreign liquid causing less winking with less consequent expression of the liquid between the lids; secondly, the secretion of mucus is smaller, and thus the solution is less diluted and less likely to be washed away; and thirdly, the conjunctiva and cornea are drier, and thus absorb the eserine more readily. The author convinced himself by special experiments of the difference in the behavior of cocaine according as it was applied before or simultaneously with the eserine or pilocarpine, and the above explanation is the only one which appears to him adequate to explain the apparent paradox.—*The Lancet*, January 8, 1887.

URETHAN IN THE TREATMENT OF MENTAL DISEASES.

OTTO and KÖNIG have given this drug in various cases of mental disease, with the following results:

In a case of great excitability in a woman who had been paralyzed, urethan was given in doses from 1 drachm to 2 drachms without any apparent effect. Larger doses produced very unpleasant after-effects in gastric symptoms. In excitability of idiotic children it was given with good effect; in children from 4 to 10 years old the doses ranged from 8 to 16 grains in the younger, from 20 to 40 grains in the older.

In the treatment of men who had been paralyzed its use was quite without effect.

König concludes that paraldehyde in such cases is much better; in large doses it also produces gastric disturbance, and when used for a long time cerebral impairment.

Rottentiller, in Budapest, has had much better results from the subcutaneous use of urethan with from one to three injections of one-fourth syringeful of a thirty per cent. solution. A restful sleep of six or eight hours followed, and the injection was unattended by unpleasant after-effects locally.

The experiences of the writers did not lead them to expect any well-defined and practical effect from the use of urethan.—*Zeitschrift Apotheker-Vereins*, No. 33.

THE TREATMENT OF CERTAIN FORMS OF VOMITING.

There are few disorders which cause more discomfort and distress than those accompanied with incessant attacks of vomiting; there are few disorders which try more the patience and the skill of the practitioner. DR. F. P. ATKINSON gives us in the *Practitioner* (for November, 1886) a number of points which may prove useful in relieving certain forms of obstinate vomiting.

In cases of *simple bilious vomiting* he states that a mixture containing 15 minims of solution of potassium and 4 of laudanum administered every four hours acts like a charm, and he asserts that in no uncomplicated cases will there be any vomiting after two or three doses. For the *vomiting of pregnancy* he suggests a little milk and tea, with a small piece of bread and butter or biscuit, immediately before rising in the morning, and a biscuit or two at various intervals throughout the day, whenever there is a feeling of emptiness. In vomiting from *ulceration of the stomach* the great object is to give the stomach as much rest as possible. This may be accomplished by giving very small quantities of peptonized milk or koumiss at short intervals; thus a teaspoonful of the above may be mixed with cold water, and given every four hours. Dr. Atkinson further recommends that the body should be oiled night and morning to help nutrition, and covered with warm clothing to prevent cold. Later on, when the pain has almost subsided, various simple foods may be allowed. When the vomiting is very urgent, of course the stomach should be given entire rest, and peptonized meat enemata should be administered.

In the vomiting which occurs in *infants brought up by hand*, the most frequent cause is found in the inability to digest the casein of the milk. In such cases it is advisable to use one of the many peptonizing powders now on the market, or the following may be given: Two tablespoonfuls of whey, two tablespoonfuls of water, and one tablespoonful of cream; if there be some diarrhoea, a little meat juice may be given three or four times daily, while the body should be oiled night and morning.

THE ALCOHCLIZATION OF WINES.

In the session of the Academy of Medicine of France held November 30, 1886, the Academy discussed at length the question of the reinforcing of wines with alcohol, and, after a long controversy, arrived at the following conclusions :

1. The addition of pure alcohol to wines in quantities not exceeding two degrees may be allowed ; but amounts greater than this cannot be tolerated.

2. Addition of alcohol is dangerous, not only because of the quantity and quality of poor alcohol used, but because it destroys confidence and perpetuates fraud.

3. Alcohols commonly called good increase considerably the injurious effects of brandy and liqueurs ; alcohol added to these liquids should be absolutely pure.

4. The Academy called the attention of the authorities to the necessity of reducing the number of smaller warehouses for keeping and altering wines, and of putting in active operation laws against drunkenness.—*Bulletin de l'Académie de Médecine*, No. 48.

A NEW METHOD OF EXCISION OF THE KNEE.

At a recent meeting of the Medical Society of London, Mr. HERBERT ALLINGHAM (*Lancet*, December 18, 1886) read a paper, and showed cases illustrating a new method of excision of the knee. The operation consists in making a vertical incision over the joint in front, beginning two or three inches above the patella, and prolonged over the patella down to the tubercle of the tibia. The knife splits right through the quadriceps tendon above the patella into the synovial pouch there. The soft tissues over the patella are divided to the bone, the knee-cap sawn through, dividing it into two lateral halves, then the ligamentum patellæ is also split down to the tubercle of the tibia. By this means the joint may be thoroughly exposed by drawing outwards each half of the patellæ and associated structures to its corresponding side of the joint. The two halves of the patella are wired when the operation is finished. He claimed the following advantages for the operation: 1. The attachments of the fascia lata, the lateral ligaments, and the prolongation of the vasti to the tibia and fibula are not divided, and consequently there is much more support to the joint during the healing process, and when the leg is well. 2. Above

the patella the synovial pouches are well opened, and all the synovial membrane can be thoroughly removed. 3. Dislocation of the tibia backwards and tilting of the femur forwards, which commonly occur after the operation, are thus prevented. 4. The joint and the end of the bones can be thoroughly examined, which was not possible by the method of lateral incisions. 5. The undivided quadriceps is a strong antagonist to the hamstring muscles, and should the splint be left off the leg is much less likely to become bent. 6. Progression is greatly improved, the attachment of the quadriceps being neither divided nor the muscles shortened, as must necessarily take place when either the transverse H- or U-shaped operation is performed. 7. And, above all, as we hope after excision to obtain movements in the knee-joint, the chances, Mr. Allingham thought, of such a result being brought about will be greatly facilitated by the operation described. In future operations Mr. Allingham said he would remove thoroughly the whole synovial membrane, and only dig out with a gouge the diseased spots on the cartilage, and should not in any way interfere with any of the cartilage that looks healthy. If the crucial ligaments are not extremely diseased they should be left undivided. The joint should be kept at absolute rest until the wound has healed, when passive motion may be commenced.

TREATMENT OF BRIGHT'S DISEASE.

SEMMOLA, of Naples, in an article in the *Wiener Medizinische Blätter*, No. 49, advises strongly against allowing a patient who is suffering from nephritis to come in contact with cold in any avoidable way. Such patients are excessively sensitive to cold, and cold baths are followed by great shock and depression. Violent massage and exercise of the muscles the author also strongly deprecates as followed by great shock and weakness.

He would advise the patient to live in a dry and equable climate ; to strictly avoid all exposure or going about in severe winter weather ; to practise mild gymnastics in a comfortable room rather than venture into a temperature below 18° or 20° C. The author emphasizes the remarkable sensibility of the skin of the sufferer with Bright's disease to all variations of temperature. Sodium iodide and chloride is advised in doses as large as tolerated. When, after two or three weeks, albumen has not entirely disappeared and dropsy

has been relieved, phosphates of sodium or calcium are given in quantities as large as 40 grains or a drachm daily. The efficacy of these drugs the author believes consists in their power to promote the assimilation of albumen.

The methodical inhalation of oxygen, which Semmola has urged since 1867, has been repeatedly proved to be of the highest benefit. Albumen soon disappears after its use, and although casts may remain in the urine, the patient's general condition is so much improved that the author thinks we have here an argument for the dyscrasic or hæmatogenic origin of Bright's disease.

All astringents are considered not only valueless but also injurious. Especially is the action of ferrum sesquichloratum and plumbum aceticum thought injurious because of their astringent influence on the capillaries of the skin.

HYOSCINE AS A CEREBRAL SEDATIVE.

DR. J. MITCHELL BRUCE, writing in the *Practitioner* (November, 1886), is able to confirm the statements already made as to the value of hyoscine as a cerebral sedative. His experience shows that there can be no doubt about the rapid and thoroughly complete effect which it possesses in quieting delirium. With the exception of this drug, our present sedatives are not sufficient to meet every case. The bromides, chloral, and morphine, which constitute the entire group of sedative drugs to which we have recourse with any feeling of confidence, will often fail us one after the other in urgent cases. The bromides have not the power, while chloral and morphine are dangerous in many cases, and dare not be given. In such cases Dr. Bruce believes that hyoscine will be thoroughly reliable, and that in cases of troublesome, noisy delirium there is no treatment at once so prompt, successful, and safe as a hypodermic injection of hyoscine. As might be expected, its use is not entirely unattended by some disadvantages. Thus, within half an hour after the administration of from $\frac{1}{100}$ to $\frac{1}{75}$ of a grain it may cause failure of respiration in the form of rapid, shallow breathing, or often Cheyne-Stokes rhythm. It has also been observed that cough has been noticed on the nights that hyoscine has been given in delirious cases. The pulse may become weak, the face livid, and the pupils dilated, the whole appearance of the patient being calculated to cause anxiety. There is not, how-

ever, a case on record in which death has been attributed to an overdose of this drug, and it is rarely necessary to give large doses, Dr. Bruce having found that the $\frac{1}{100}$ of a grain will often produce full effects. Again, hyoscine does not produce any dryness of the skin and throat, but occasioned, in Dr. Bruce's experience, distinct increase of perspiration, indicating some radical difference between the action of this alkaloid and other members of the atropaceous group.

COCAINE AS AN ANÆSTHETIC IN LABOR.

FISCHEL, of Prague, has used cocaine in six cases of labor, with two negative, one fully successful, and three partly successful results. He regards it as an adjuvant to chloroform. Cocaine is useful only in annulling pain caused by the tension upon the maternal tissues. Fischel proposes to apply a four or five per cent. solution through a speculum to the tense and dry tissues. When abundant liquor amnii has escaped, the powdered drug, mixed with an accompanying neutral powder, is advised.—*Wiener Med. Wochenschrift*, December 11, 1886.

NASAL TREATMENT OF WHOOPING-COUGH.

A definite idea has of late gained ground as to the nature and origin of whooping-cough. The idea may or may not be pathologically correct; but the treatment founded on it is decidedly of a rational description. What is more to the practitioner, this treatment is said to prove remarkably successful. Correctly speaking, the idea is compounded of at least two factors. One of these is fully as familiar as whooping-cough is common. Micro-organisms are the cause of the affection. The microbe effects an entrance into the economy from a special site, and that site of entrance is the soft tissues of the nasal fossæ. The rational therapeutics is founded on formulæ of an equally explicit character. Antiseptics or germicides will destroy the living germs. They should be used early, and their sites of action are the nasal fossæ. The number of remedies already recommended is sufficiently striking. The method at present in greatest favor appears to be insufflation. Convenient contrivances of different designs for effecting the insufflation may be met with in great variety at the surgical instrument makers. A clumsy but successful

insufflator may be contrived by rolling a spill of paper, inserting a little of the powder to be employed at the end that enters the nostril, and supplying the motive force by the parent's or operator's puff of breath. But the puff-balls or regular insufflators are effective and not costly. Iodoform, salicylic acid, and boracic acid are the three antiseptics that appear to be most in vogue. They should all be very fine, almost impalpable powders. Nasal douches are very effective if they can be managed, as in older and not too nervous children. The most effectual douche of antiseptic kind appears to be the 1 in 500 corrosive sublimate. Care is to be taken that no appreciable quantity of this solution is swallowed. Some practitioners employ simple nasal douches in the earliest stages,—say, a drachm of Condyl's fluid or of common salt to the pint of water. And this is done as much to mechanically wash away secretions with contained contagia as to destroy the germs. Weak solutions of tincture of iodine and of alum are also used. These lotions may be syringed into the nasal passages, or the children may be induced to snuff the lotion up from the palm of the hand. Older children may be taught to take the powders as "snuff." Repeated applications of any of these methods are necessary to insure thorough topical treatment in the early stages of the catarrh. The antiseptic agents may also be applied, as in young infants, by means of camel-hair brushes charged with ointments, lotions, or glyceroles. It is necessary to clear away all secretions and scabs first, by syringing or anointing with oil. The agent is then directly applied to the bare congested surface of the mucous membrane. An ointment of half a drachm each of iodoform and eucalyptol to an ounce of vaseline is highly commended by some. The boroglyceride may be used in similar fashion, also lotions of corrosive sublimate. Any of the antiseptic solutions may be atomized by the steam- or hand-spray, and inhalations effected through the nostrils. It is doubtful whether the theory of this fashionable method is correct; but supposing it should be, it is equally dubious whether the good that results may not be from the mere treatment of the catarrh as such, apart from its supposed cause. A pledget of cotton-wool, or a chamomile flower placed in the nostril to prevent the access of air, alleviates the symptoms of an ordinary rhinitis. So it may be with the various applications, the principal of which we have mentioned. Cocaine is now widely used as a

four or five per cent. solution painted on to the nasal and pharyngeal mucous membranes, not only in whooping-cough, but in simple or severe catarrhs.—*Lancet*, January 15, 1887.

INVESTIGATION CONCERNING PERISTALSIS IN THE INTESTINE AND THE ACTION OF CATHARTICS.

Hess, of Munich, discusses at some length the theories which have been advanced to explain intestinal peristalsis and the action of laxatives, and describes his own experiments upon these points.

The original explanation of Liebig, that endosmosis and exosmosis governed the action of laxatives, and the theory of Aubert, that peristalsis depended upon an increased nervous reflex, have been defended and modified by other writers, some of whom have laid great stress upon the influence of increased secretions, and the hinderance to the absorption of these secretions which exists in venous stasis and accelerated peristalsis (Thiry). According to Vulpian, Lauder Brunton, Brieger, and Hay, laxatives cause increased peristalsis, as do also small doses of drastic purgatives; in large doses drastics cause an inflammatory exudate and hypersecretion; the neutral salts cause an outpouring of water into the intestine which is not a simple transudation, but a hypersecretion as well.

The author does not consider the present series of experiments as concluded, but as introductory to a more extended series. His method was as follows:

In a dog of medium size a gastric fistula was made, whose opening was near the pylorus. The finger introduced into the fistula was grasped by the muscle of the pylorus, and the beginning of the duodenum was accessible through the fistula. In the first portion of the intestine was placed a small rubber balloon, which terminated in a projection or handle to which a rubber tube could be attached; the capacity of this balloon, when moderately distended, was twenty to thirty cubic centimetres of fluid. To its tip or handle was attached a long rubber tubing, graduated in centimetre lengths and wound with thread to prevent its distention. After its introduction the balloon received from a graduated syringe a registered amount of water. The balloon sank into the pyloric opening, and began to pass through the intestine, advanced by the peristaltic action of the bowel. Its rate of advance could be easily measured by the graduated tube; it

could be emptied by this tube, or further distended without removing it from its place in the intestine.

It is evident that but sufficient tubing was needed to traverse the entire intestine; the animal showed no signs of discomfort. By checking the progress of the balloon, it could be used as a tampon for dividing the intestines; by allowing it to be expelled, fluid could be injected into the lower bowel through the tubing.

To ascertain the mode of the normal peristalsis two series of observations were undertaken, in the first of which the balloon contained forty-five cubic centimetres of water, in the second twenty-two cubic centimetres.

The balloon in the first instance was filled *in situ*, and a laxative mixed with ferrocyanide of potassium administered.

An examination of the fæces showed the coloring-matter, and proved that the distention of the balloon was not so great as to entirely occlude the intestine. In twenty-nine hours and fifty minutes the balloon had proceeded a distance of one hundred and forty-nine cubic centimetres, where it stopped, and, after remaining immovable for several hours, was finally emptied, and expelled by a soap-and-water clyster. There was every reason to suppose that its lodgment was at the ileo-cæcal valve, which could not be passed by a ball of its dimensions.

The next experiment was with the balloon containing twenty-two cubic centimetres of water, and resulted in the passage of the balloon nearly to the anus, a distance of two hundred and twenty centimetres in the animal used, in twenty-three hours and twenty-five minutes. It was, as before, expelled by an enema.

The experiments of Crampe have established the ratio between the body length and length of the intestines at eight and one-half times. By this proportion the length of the intestines in the animal the subject of this experiment was six hundred and eighty centimetres. A post-mortem measurement gave five hundred and thirty centimetres as the length. The balloon passed less than two hundred and fifty centimetres in traversing the intestines, and the difference is accounted for by the contracted condition which peristalsis induces. This condition of contraction was followed by relaxation behind the balloon, which rested in a sac of intestine for varying intervals. This was demonstrated by the difference in the distance traversed at ten-minute intervals during the progress of

the experiment. Subtracting the one hundred and forty-nine centimetres from the two hundred and twenty centimetres passed by the balloon the second time, we have seventy-one centimetres as the length of the large intestine, the distance from the anus to the ileo-cæcal valve. Post-mortem measurement gave this distance seventy-three centimetres.

It was observed that peristalsis began a short distance below the pylorus, and was, as has been said, intermittent in pauses of even an hour's duration. It was also much more vigorous near the pylorus, and became less active as the distance from the stomach increased, as Nothnagel had shown previously. It was noticeable that the bolus which moderately filled the intestine passed more rapidly than the larger one which distended it.

Expiration favored peristalsis. In the large intestine the balloon moved much more slowly than in the small bowel.

The relative vigor of peristalsis during day and night was 3 to 1.

Long pauses in the movement of the balloon were observed with some animals, which could not be explained.

As the balloon progressed more deeply into the bowel a secretion was established in the stomach, which was thought to be the result of reflex action.

The force exerted in normal peristalsis was measured by passing the rubber tubing over a pulley, and attaching to its extremity a bag in which shot was placed. The following were the results:

Just within the pylorus the force exerted by the intestine sustained two hundred and twenty-eight and one-half grammes, or about seven ounces. As the distance from the stomach increased, the weight sustained and raised diminished to 90.4 grammes and 75.5 grammes. While the author does not consider this portion of his experiment as at all conclusive, yet it illustrates forcibly the peristaltic power of the intestines.

In ascertaining the mode of action of laxatives the rubber tampon (the balloon) was allowed to go some distance in the intestine, and then kept stationary. A cathartic was given, and the phenomena attending its action in the presence of the tampon were observed, and, with the exception of ox-gall, none caused diarrhœa, while their entrance to the small intestine only was allowed.

When the balloon was collapsed, diarrhœa generally began promptly as soon as the drug had gone farther into the large intestine. As before, it was endeavored to *fill* the intestine

without distending it, and potassium ferrocyanide was used as previously. In addition to those cases in which no diarrhoea was caused by the descent of the laxative material, there was a proportion of cases in which the cathartic seemed reabsorbed by the intestine before it reached the large intestine.

The list of laxatives used in experimenting included sodium sulphate, castor oil, calomel, senna, croton oil, colocynth, gamboge, and oxgall. Each drug was given first, without its confinement in a particular part of the intestine, and its effect, when given in this manner, was contrasted with that produced when, by the agency of the balloon, its effect was limited to a particular portion of the bowel. At the conclusion of his experiments the author repeats as follows what we have stated: "All laxatives with which experiments were made, especially in active doses, occasioned no diarrhoea when prevented by the balloon used from going into the large intestine."

These laxatives effected the results which followed their ingestion by a direct action on the mucous membrane of the intestine. Those drugs which cause laxative effects when injected into the blood are absorbed too slowly and in too small quantities when introduced into the intestine to produce their previous effects.

Supposing catharsis to result from accelerated peristalsis, these experiments would tend to show that the action did not result from the contraction of long portions of the muscular coat, nor from a rapid action communicated from one muscle to another, but through the irritation of successive portions of the mucous membrane of the intestine. It is also a reasonable supposition that the peristaltic distention, which was always present just above the balloon, was disseminated through the whole of the small intestine, and excited afterwards by the cathartic in the large intestine.

The author took especial pains to avoid the paresis of the intestinal muscle, which overdistention of the balloon used might have caused through its pressure, and the balloon was allowed to play only the part of a moderate accumulation of fæces.—*Deutsches Archiv für Klinische Medecin*, Band 40, 1 Heft.

A NEW TREATMENT OF GONORRHOEA.

CASTALLAN, of St. Mandrier Hospital, starting with the view, now popularly entertained, that gonorrhoeal urethritis is a parasitic disease, and being led by observation to believe

that the microbe can only live in an acid medium; finding, moreover, that in this disease the discharge is, as a rule, acid, proposes to treat gonorrhoea in the acute stages by urethral injections of sodic bicarbonate, three or four injections being made daily of a one per cent. solution. For this treatment, which is but a logical inference from the premises, he claims remarkable success, although the cases on which it has been tried in St. Mandrier, as yet, number only a dozen. The injections of bicarbonate of sodium are commenced as soon as the discharge appears, or the patient comes under observation; the urethral secretion is tested every day with litmus-paper, and the injection is kept up till the discharge becomes alkaline or neutral. For internal treatment the patient is given flaxseed tea, with occasional doses of bromide, if there seems to be any indication for the sedative effects of this salt. His conclusions are as follows:

1. The urethral pus in the first stages of the disease is generally, if not invariably, acid; this acidity is quite pronounced.

2. The treatment by bicarbonate of sodium rapidly lessens the discharge; it also rapidly diminishes or removes the pain in micturition.

3. In old urethrites, and in those which have been treated by the usual injections, it speedily brings about a cure.—*Boston Medical and Surgical Journal*, January 13, 1887.

THE SUBCUTANEOUS AND INTRAMUSCULAR INJECTIONS OF PREPARATIONS OF IODINE IN SYPHILIS.

The rather unsatisfactory state of the therapeutics of syphilis at the present day justifies a careful attention to suggestions of improvement as found from time to time in the medical press. In addition to the exhibition of iodiform in syphilitic lesions, as discussed in a previous issue of the THERAPEUTIC GAZETTE, we now beg to review a recent paper of DR. CARL SCHADECK, of Kiew, which appeared in the *St. Petersburg Medical. Wochenschrift*, No. 29, 1886, and advocates the employment of preparations of iodine.

Schadeck instituted a series of clinical experiments with the iodides of sodium and potassium on soldiers of the Kiew military hospital affected with syphilis. There were eight cases in all, and the number of subcutaneous and deep intramuscular injections made was ninety. The largest number of injections made in one individual was sixteen (in two cases); in the other cases the number of injections was twelve (two cases), ten, nine,

eight, and seven. In seventy-nine instances the injections used were a solution of iodide of potassium; in the remaining eleven iodide of sodium was used. The employed solutions were carefully neutralized, filtered, and prepared according to the following formula:

R Potassii (sodii) iodat., gr. xlv;
Aquæ dest., fʒiiss.

This solution was daily prepared fresh, and injected by means of a Pravaz syringe, each patient receiving daily about $3\frac{1}{2}$ grains of the iodine salt. Of the ninety injections twenty-six were carried deeply under the aponeurosis of the gluteal muscles (Arcari's method), and the remaining sixty-four in the ordinary manner. The deep intramuscular injections were made without raising a fold of the integument, piercing with the needle the skin, the cellular tissue, and the fascia perpendicularly. In this manner the entire quantity of the solution was carried directly into the parenchyma of the muscle.

The principal results obtained by Schadeck's experiments, as far as they interest the general practitioner, can be conveniently epitomized as follows:

1. The pain resulting from the injection itself, or the puncture of the needle, was either quite immaterial or wholly absent.*

2. The injected solution generated invariably a painful irritation, which differed in intensity, duration, and character in the various instances.

3. In no instance appeared an abscess or inflammatory infiltration on the point of injection.

4. In two patients appeared after nine or ten injections an iodine exanthema on face, trunk, and extremities in form of small acne-pustules. This eruption disappeared almost immediately after withdrawing the applications.

5. As to the therapeutic effects obtained no palpable results could be anticipated, as the number of injections did in no case suffice to develop the full iodine action against the syphilitic lesions. It has repeatedly and conclusively been shown that iodine introduced into the system hypodermically is taken up by the bodily juices, and exerts thus its specific action. In two instances the experimenter succeeded in eliminating all syphilitic lesions by the ex-

clusive hypodermic application of the two salts of iodine.

6. Although these experiments are in themselves too scanty, and possibly too superficial to justify any definite conclusion as to the therapeutic value of the foregoing hypodermic uses of the salts of iodine, they nevertheless go far in showing that the mercurial treatment is no *conditio sine qua non* in the treatment of syphilis, and encourage further trials in the indicated direction.

A NOVEL TREATMENT OF PHTHISIS.

DR. BERGEON, of Lyons, recommends a method of treating phthisis which has, at any rate, the merit of novelty. His plan is to utilize the effects of sulphuretted hydrogen, and this he proposes to do by injecting carbonic acid gas, saturated with sulphuretted hydrogen, into the intestines. If care be taken to secure the absence of atmospheric air, no inconvenience, it is said, results from the injection even of large quantities of the mixture; absorption into the venous system and elimination by the lungs taking place very rapidly. It is claimed for this procedure that, by its means, the use of sulphuretted hydrogen is unattended with any toxic effects, and exerts its influence directly on the lungs themselves. It has been employed in a number of cases at the hospitals of Lyons, Bordeaux, and Paris, with great benefit to the patients, even in very advanced cases, and, latterly, similar observations have been made in the consumption hospitals of London, the results of which have not yet been made known. The method has been very much simplified by the introduction of an ingenious but simple apparatus whereby the carbonic acid gas is generated, and saturated with sulphuretted hydrogen, ready for use.—*British Medical Journal*, November 27, 1886.

THE DRUGS WHICH INCREASE AND DECREASE THE SECRETION OF MILK.

GIURLEO calls attention to the peculiar properties of *Ditana digitifolia*, which, he claims, possesses the power to stimulate the secretion of the mammary glands, confirming the statements published in a previous issue of the GAZETTE. The author found an opportunity to try the remedy in a number of wet-nurses, and pronounces himself as extraordinarily satisfied with the results obtained. In some instances, in which the secretion was

* In Germany the hypodermic syringes in use have all extraordinary long needles (compared with the American instrument), and are also carried into the muscular parenchyma in order to obviate pain and eventual abscesses of the cellular tissue.

almost wholly absent, the ingestion of an infusion of the plant produced a copious supply of milk.

In Italy an ethereal tincture of *Ditana digitifolia*, combined with syrup, has been known for a long while under the name of "galatiosore."

The blossoms and buds of the plant, besides, possess diaphoretic properties.

The same author asserts that *Rhamus alaternus* and *Ligustrum vulgare* have properties precisely opposite to those of *Ditana digitifolia*,—i.e., they decrease the secretion of milk. The author uses an infusion of these plants (45 grains of the leaves to 6 ounces of water), and orders for several days this quantity of the infusion to be used up twice a day. —*Journal de Médecine de Paris*, July 11, 1886.

PEREIRINE AS A TONIC.

The bark of the pao-pereiro tree is said to be a tonic and febrifuge. It contains an alkaloid which was first isolated by Ezequiel in 1838. The name of Pereirine has been given to it. The product of that name used in Brazil is an amorphous yellow powder, which is not a pure alkaloid, but contains a compound of amyl, a bitter coloring substance insoluble in water, analogous to glucose, a hydrocarbon, and another crystallized substance, probably a glycoside. Pereirine is very slightly soluble in water, to which it communicates a bitter flavor, but dissolves easily in ether. M. GUIMARAES has proved that pereirine produces the following effects: 1. A period of agitation characterized by slight convulsive trembling of the skin, irregular respiratory movements, decrease of the central and peripheral temperature and of the pulse-beat. 2. A period of functional paralysis, consisting in aphonia, diminution in the number of respirations, elevation of temperature, paralysis of voluntary movements. 3. A period of complete paralysis ending in death. Pereirine, as sold commonly, is impure. M. Ferreira has administered doses of two grammes a day in cases of persistent paludal infection.—*British Medical Journal*, January 1, 1887.

ANTIFEBRIN AS ANTIPYRETIC AND ANTISEPTIC.

The researches of DR. G. KRIEGER with antifebrin, as published in the *Centralblatt für Klinische Medizin* (October 30, 1886), seem not only to corroborate the claims of Heppe

and Cahn as to the antipyretic virtues of the drug, but have also yielded the fact that the new remedy possesses energetic antiseptic properties.

Antifebrin was found to be soluble at a temperature of 60° F. in one hundred and sixty parts of water, and at a temperature of 212° F. in twenty-five parts of water. In acids it is scantily soluble in presence of cold, but readily so if heated. On cooling, the saturated solution assumes a gelatinous consistency through precipitation of the crystals. More easily than in water antifebrin is soluble in ether, alcohol, and alcoholic liquids, without impairing their taste.

Krieger made his observations in the eighteen following cases: Typhoid fever, four cases; intermittent fever, three; croupous pneumonia, three; acute articular rheumatism, three; pleurisy, two; diphtheria, one; puerperal fever, one. Besides, the drug was exhibited in several cases of facial neuralgia, where it caused the immediate disappearance of otherwise regularly-appearing paroxysms.

In order to determine the comparative value of antipyrin and antifebrin, a series of observations was made in various cases of typhoid fever, and showed—differing somewhat from the results obtained by Cahn and Heppe—that 7 grains of antifebrin corresponded in duration and magnitude of effect to 15 grains of antipyrin, though the former requires a longer time for the manifestation of intense action.

Krieger adds to his paper a number of clinical charts illustrative of the absolute and comparative physiological properties of antifebrin. These charts show that a slight action set in very soon after ingestion of the drug. An intense action, however, cannot be observed before the third hour, and between the sixth and the tenth hour all action has disappeared. Simultaneously with the temperature the frequency of the pulse is lowered, while its magnitude and tension increase. The author states that no secondary symptoms were ever recorded in the course of the antifebrin treatment, excepting a regularly discernible cyanosis of the cheeks and the visible mucous membranes. Vomiting, or even an inclination to vomit, such as frequently attends the ingestion of antipyrin, was likewise not observed. Sweating has been seen in a few instances, and a great appetite in numerous cases as results of this treatment.

The action of antifebrin, though it was in no instance negative, manifests itself quite

differently in different affections. Typhoid and intermittent fever receive the greatest reduction of heat. In pneumonia, pleurisy, and especially in puerperal fever, the antipyretic properties of antifebrin are less conspicuous. The entire absence of rigors in the reascend of temperature is an especial feature of the antifebrin action.

It is difficult to as yet define the exact indications for antifebrin, and to explain the *modus operandi* of its physiological action. Against any action from the part of the gastric juice speaks the wholly negative result obtained in a case of so-called artificial digestion (by means of pepsin and muriatic acid at 92° F.). The cyanosis, however, above referred to justifies the assumption that at least a part of the antifebrin is changed back into aniline.

As to the dose, Krieger advises to begin with 10 to 15 grains, and to gradually increase it; 50 grains were in many instances given *pro die* with perfect impunity.

A number of surgical cases coming under the observation of Krieger convinced the author that antifebrin possesses also distinct antiseptic virtues. In these cases the drug was used either as a powder or dissolved in ether or collodion. The closed wounds thus treated healed invariably *per primam intentionem*; the open ones showed little or no irritation and suppuration.

The action of the drug upon micro-organisms will form the subject of a later publication of Krieger. A more extensive application of antifebrin for internal and surgical purposes is facilitated by the extraordinary cheapness of the drug.

THE CURABILITY OF ALCOHOLIC CIRRHOSIS.

According to a Paris correspondent, a short time since M. TROISIER communicated a case to the Société Médicale des Hôpitaux in which the ascites resulting from cirrhosis of the liver had disappeared under the influence of iodide of potassium and strychnine, and the visceral lesion itself had seemed to be cured. In the discussion which ensued it was pointed out that ascites sometimes passes away spontaneously in the course of a cirrhosis, and, on the other hand, the affection of the liver may go through all its phases without giving rise to peritoneal effusion. M. Troisier now goes further. He asks whether there does not exist a particular form of alcoholic cirrhosis in which the lesion,

stopping short of destruction of the liver-cells, is susceptible of retrogression; and he relates another case in support of this hypothesis. A confirmed drinker, aged 68, was under the care of a colleague, and presented all the symptoms of hepatic cirrhosis. Between the months of December and September one hundred and sixty-five litres of fluid were removed by tapping at different times. At the present time the peritoneal cavity is empty, the liver slightly enlarged, and the patient in excellent health. M. Bucquoy said that he had seen several similar cases, and he entertained no doubt that other members of the Society had had a like experience.—*The Lancet*, December 25, 1886.

INDIAN HEMP AND BELLADONNA IN WHOOPING-COUGH.

VETLESEN recommends in the *Norsk Mag. f. Lægevidenskaben*, 1886, No. 9, the following prescription as a cure for pertussis:

R Extr. cannab. indic., gr. xv;
Extr. belladonnæ, gr. vii;
Alcoh. absol.,
Glycerini, aa fʒiiss.

To be given to children of 8 months to 1 year in 4- to 5-drop doses; 1 to 2 years in 5- to 8-drop doses; 2 to 4 years in 8- to 12-drop doses; 4 to 8 years in 10- to 13-drop doses; 8 to 12 years in 12- to 15-drop doses; over 12 years and to adults in 15- to 20-drop doses.

The medicine is to be taken either only in the evening, or evening and morning. In children younger than 8 months Vetlesen has not yet tried the remedy. The number of cases thus treated is one hundred and sixteen; in eighty-three (71.6 per cent.) the result was favorable, and in thirty (25.9 per cent.) the result was excellent. Injurious effects have never been observed. Controlling experiments have shown that neither of the two drugs, when given alone, could bring about the favorable results attending their combination.

CARBOLIC ACID IN WHOOPING-COUGH.

DR. F. P. ANDERSON, of Grosse Isle, writes to us that he has treated a number of cases of pertussis during the past three months with small doses of carbolic acid, and in one case only did he resort to other remedies.

In several cases in the same household the paroxysms of coughing and vomiting were arrested so promptly as to cast doubt on the

correctness of his diagnosis, a doubt dispelled by temporarily withholding treatment in one subject.

The triturated tablets containing one-tenth grain of carbolic acid were administered generally, and introduced without objection into the child's mouth. To an infant of 3 months of age a half tablet (gr. $\frac{1}{8}$) was given every three or four hours; to children from 1 year to 3 years of age the dose is one tablet. Care must be exercised in increasing dose for age.

The cases treated during the fine weather of October and November were discharged cured in from two to three weeks, although from the commencement the intensity of the symptoms was modified. All but one were taken in hand as early as the affection was recognized; this excepted one had been whooping and vomiting for several days, and yielded almost as readily as the other.

The weather throughout was favorable, but many patients were of the poorest class, and received little care.

Attention to this use of carbolic acid was directed first by Dr. Macdonald, of Liverpool, England, as long ago as 1881.

THE TREATMENT OF TYPHOID FEVER BY CORROSIVE SUBLIMATE.

In the *Deutsches Archiv für Klinische Medizin* of November 30, 1886, GLÄSER, of Hamburg, reports the results obtained in twenty-three cases of typhoid fever by the use of corrosive sublimate. The cases selected were those in which the diagnosis was plain, and which were of at least moderate severity, and which had not advanced so far that medication was useless. The number of cases treated was too small to be of value in statistics of mortality, but large enough to give a result as to the effects of the drug upon the principal symptoms of typhoid.

The following were the results obtained:

1. In twenty-three cases five deaths, a mortality of twenty-one per cent.

2. Four cases showed a fall in temperature to the normal before the nineteenth day of illness, on the thirteenth, fifteenth, sixteenth, and nineteenth days respectively after sublimate was given on the sixth, eighth, and tenth days.

Two parallel cases which had no sublimate showed a fall of temperature on the fifteenth and sixteenth days.

Six cases showed a fall of temperature to the normal on the twentieth to twenty-third days after two doses of sublimate on the

eighth day, and on the ninth, tenth, eleventh, and fifteenth days, one dose.

Five parallel cases, without the sublimate treatment, showed similar defervescence.

In eight further cases the fall to normal temperature came later; two on the fifteenth day, one on the sixteenth, two on the seventeenth, one on the eighteenth, one on the twentieth, one on the twenty-second day after taking the sublimate.

3. Sublimate had no influence upon the condition of the tongue; in eight cases it remained dry, and did not alter until defervescence occurred.

4. The roseola of typhoid was in eleven cases aggravated by sublimate to such a degree that the face was affected, and the cases resembled measles.

5. The general condition of the patient was not in the least improved.

The influence of the treatment on the duration of the illness and its relapses is best shown by the following table:

Day of administration.	Duration of fever.	Day of administration.	Duration of fever.
6.....	60 days.	10.....	51 days.
7.....	66 " (Relapse.)	11.....	74 " (Relapse.)
8.....	51 " (Relapse.)	12.....	89 " (Relapse.)
9.....	41 " (Relapse.)	13.....	51 "
	48 " (Relapse.)	14.....	64 "
	90 " (Relapse.)	15.....	59 "
	44 " (Relapse.)		51 "
	45 " (Relapse.)		
	64 " (Relapse.)		

The question of greatest interest in these reports is the dosage and the bearing of the cases upon the possibility of effectually destroying the bacillus of typhoid fever in the organism. When the amount of blood (at one-thirteenth of body-weight) to be disinfected is considered, we find that using a solution of sublimate, 1 to 4000 or 5000, its proportion to the blood would make the actual proportion of mercurial to the blood $\frac{1}{10400}$, which is a solution inert as a parasiticide. In the series of cases cited it was given in eight doses *pro diem*, the total given being three-tenths of a grain in a day and a half, the solution used being 1 to 4000 or 5000.

The series illustrates in an interesting manner the difficulty of practically disinfecting the blood while still within the body without at the same time destroying life.

THE ACTION AND THERAPEUTIC VALUE OF VEGETABLE ASTRINGENTS.

The term astringent in its widest sense as including styptics may be defined as referring to substances which either when locally ap-

plied or after absorption into the blood cause contraction of the tissues, diminish secretion, and arrest hemorrhage. Those which so act after absorption into the blood are known as remote astringents, and include acids, many salts of the heavier metals, ergot, digitalis, gallic and tannic acids, and many of the substances containing them. To the last of these it is customary to apply the name of vegetable astringents, and their mode of action and therapeutical value has been carefully investigated by DR. RALPH STOCKMAN, who publishes his results in the *British Medical Journal* for December 4, 1886. His paper includes an elaborate series of experiments as to the mode, form, and amount in which these bodies are absorbed and circulate in the blood, and are excreted, and as to their action on the blood-vessels and circulation.

Our space will not permit an analysis of these experiments, for which we must refer the reader to Dr. Stockman's paper. His conclusions as to the therapeutic value of vegetable astringents are, however, of considerable interest and value. Considering gallic acid first, he says that either when locally applied, or after absorption into the blood, gallic acid evidently exercises no other action than that of a weak inorganic acid, and certainly has no claim to any special action as an astringent. The only action which it can have in this direction is the power which it possesses, in common with all other acids, of diminishing the alkalinity of the blood, and thereby increasing its tendency to coagulate. Stronger acids, however, will act much more powerfully in this direction than it does. Any influence in lessening the calibre of the blood-vessels, either by peripheral or central action, must be denied to it. When locally applied, the fact that it does not precipitate albumen must prevent it having any influence on a catarrhal inflammation.

As regards tannic acid, the matter is somewhat more complicated. Locally applied, its action for good depends on its power of precipitating albumen, the layer of tannate of albumen which is formed acting as a protective to the underlying mucous membrane. To this action is due its value in catarrhal inflammations of the alimentary canal, and in discharging surfaces generally.

The preceding experiments show, however, that its usefulness is limited to such cases, and that as a remote astringent it is valueless. In weak solution and uncombined its action on contractile tissues, such as the vascular walls, is simply that of a dilute acid, while it

is only when stronger solutions are used (much stronger than can ever exist in the blood, even if it were not in combination there) that its power of precipitating albumen comes into play. When its chemical affinities have been satisfied by neutralizing it with a base or with albumen, it is no longer capable of precipitating albumen, and exercises, therefore, little or no influence on the parts with which it comes in contact.

Independently of these considerations, the very small quantity in which it exists at any one time in the blood, and that in combination, must also militate against its having any remote action. As we have seen, the only channels of excretion besides the bowel are the kidneys, and hence it is hardly possible that it can have an astringent action on any of the other mucous membranes, such as the bronchial. It is now almost an axiom in therapeutics that substances which do not possess a very decided general action can affect only those mucous membranes by which they are excreted, and it is improbable that tannin is any exception to this.

With regard to its action on the kidneys, it is conceivable that it may have a favorable influence in diminishing albuminuria, but even this is to be regarded as doubtful. Many eminent clinicians have expressed disbelief in its value, and the only cases which the author has been able to find, in which the amount of albumen in the urine was carefully estimated from day to day, tend to confirm this view. They are four cases of chronic Bright's disease reported by Briese (*Deutscher Archiv. f. Klin. Med.*, xxxiii., p. 220, 1883) in which the administration of tannate of sodium for long periods had no influence, either on the amount of urine or the albumen present in it.

FATAL POISONING FOLLOWING TWO VAGINAL DOUCHES WITH CORROSIVE SUBLIMATE SOLUTION.

FLEISCHMANN, of Prague, reports the following instructive case: A perfectly healthy primipara, aged 17, exhibited no symptom of kidney-disease or of any other complication of pregnancy. To disinfect the vagina before labor two douches of 1 to 2000 solution of sublimate were given, one before and one after examination by a midwife. It was noticed that a small amount of bloody mucus was expelled from the vagina after the douches. In a few hours abdominal pain, diarrhoea, and a rise of temperature occurred, all the symptoms and lesions of mercurial poisoning developed, ne-

phritis, salivation, and continued diarrhoea, and, after giving birth to a living child, the patient died in coma on the ninth day after the douches were given. The pathological anatomical diagnosis made at the autopsy was "corrosive sublimate intoxication, acute nephritis, dysentery, stomatitis and pharyngitis in the stage of ulceration, parenchymatous degeneration of heart and liver, lobar and lobular pneumonia, bilateral, acute cystitis."

On investigation it was found that after receiving the douche the patient had left her bed and gone about her work in the ward. It is not probable that any considerable amount of fluid remained in the vagina after the douche, as all ordinary precautions were taken to secure its expulsion. It is, however, quite possible that some of the fluid may have gone into the uterus and become absorbed by any superficial lesions which had occurred in the beginning dilatation of the os uteri.

It was also true that the patient had diarrhoea before the douches were given, and in his remarks upon the case Fleischmann calls attention to the danger attending the use of sublimate in puerperal patients in whom any lesion or disordered condition of the kidneys or bowels exists. He quotes the words of a well-known obstetrician, who asserts that the use of sublimate should be limited to the disinfection of the external genitalia and hands and instruments.—*Centralblatt für Gynäkologie*, No. 47.

THE MYDRIATIC PROPERTIES OF HYDROBROMATE OF HYOSCINE.

MR. JOHN TWEEDY states in the *London Lancet* for December 4, 1886, that he has found that a few drops of hydrobromate of hyoscine in a half of one per cent. solution proved to be a rapid, powerful, and unirritating dilator of the pupil alike in the healthy and in the inflamed iris, and a paralyzer of the accommodation. Notwithstanding its great activity, when given internally or subcutaneously, he has not yet met with any instance of its producing toxic effects, such as occasionally follow the use of duboisine, though these contingencies may be possible with stronger solutions. Mr. Tweedy has found that the action of hyoscine is almost three times as rapidly produced as by atropine in removing the "nearest point," in paralyzing accommodation and in fully dilating the pupil, while the effects of hyoscine also last longer than those of atropine, and are not so easily counteracted by eserine. The indication seems to be that if hyoscine is to find a place

in ophthalmic therapeutics, it will be chiefly in cases of iritis and in other conditions where it is desirable to produce as much dilatation of the pupil as possible, and for as long a time as possible.

It is further worthy of note that the application of hyoscine to the eye does not seem to cause the unpleasant taste and feeling in the throat which often follows the use of atropine.

THE ANTISEPSIS OF THE HANDS.

BELAIEFF; of Kiew, recommends the following as a sure and easy method of cleansing and disinfecting the hands:

Before the disinfecting fluid is applied the hands are thoroughly rubbed with a vaseline salve containing the coloring-matter called aqua-marine, in the proportion of 1 to 5 or 8 of vaseline.

The nails and spaces about the nails should be thoroughly filled with the salve, and its color affords a good indication of the thoroughness of its application. The hands are then well scrubbed with soap and brush until every particle of color has disappeared, when a thorough douching with solution of corrosive sublimate, 1 to 2000, completes the process.

Kümmall has stated that an efficient disinfection of the hands occurs when they are brushed for three or five minutes with potassium soap, and then thoroughly washed with three or five per cent. solution of carbolic acid, one-tenth of one per cent. solution of sublimate, or one-third of one per cent. solution of thymol.—*Pharmaceutische Post*, December 11, 1886.

CALOMEL AS A DIURETIC.

The virtues of calomel have in these days come to be somewhat undervalued, a reaction doubtless from the indiscriminate prescription of former times. DR. MENDELSON (*Deutsch. Med. Woch.*, No. 45) calls attention to its value as a diuretic, especially in cardiac dropsy, basing his remarks upon papers recently published by Dr. Jendrassik, of Pesth, and Dr. Stiller, already fully described in the *GAZETTE*. The former, having noticed the marked diuresis which ensued in a severe case of cardiac dropsy after the administration of jalap and calomel, found by further observation of other cases that this effect was due to the calomel and not to the jalap. In the great majority of the cases the daily quan-

tity of urine reached from two to five or more litres on the second to fourth day of calomel treatment. Stiller's experience is confirmatory of this, and Dr. Mendelsohn adds his own testimony to the value of the prescription. He says that when calomel is prescribed in doses of from 0.2 to 0.3 gramme (*i.e.*, 3 to 5 grains) three times a day, diuresis occurs within eight hours. It is not necessary to induce salivation to get this result, which often takes place with surprising rapidity; the anasarca and serous effusions disappear, and the patient is much relieved. It is said to be even more effective than digitalis, squills, and other remedies in certain cases, especially when the pulse-tension is not very low. Calomel does not, however, act through the heart, and is often advantageously combined with digitalis.—*The Lancet*, November 20, 1886.

INCONVENIENCES IN THE USE OF TINCTURE OF IODINE.

The *Répertoire de Pharmacie* for 1886 describes a method of removing the disagreeable yellow stain which remains after the application of iodine:

In the case of the hands where the skin has become hardened we can employ dilute ammonia, soda, charcoal, or common soap; but in treating women whose skin is tender, and in those parts of the body where the integument is not hardened, we prefer the sulphites, the bisulphites, or alkaline hyposulphites, substances inodorous and non-irritating, which absorb iodine by both their acid and their base.

We have used especially the sulphite of sodium in solutions of $\frac{1}{16}$ to $\frac{1}{8}$. This is pencilled upon the place where the iodine has been applied or used in compresses. In a few moments after application the pain and irritation caused by the iodine have disappeared.

EXPERIMENTAL RESEARCHES ON THE BIOLOGICAL ACTION OF BERBERINE.

CURCI's experiments lead him to the following conclusions (*Annali di Chimica e de Farmacologia*, July, 1886): Berberine has a paralyzing action on the brain, and especially on the voluntary motor centres, and on the centre for food appetite. It has a weak action on the sensitive centres. On the spinal cord and on the reflexes it acts late,—that is, when the blood circulation is very languid and the

heart is nearly paralyzed. This is in mammals. In batrachians the reflexes persist even after the arrest of the circulation. At the time it acts on the respiratory centres, at first exciting and then paralyzing them. The action of berberine on the circulation is rapid and energetic, the vessels are paralyzed, and the blood rushes to the periphery. The arterial pressure falls to zero, the heart beats more frequently, and the temperature falls. The vaso-motor nerves are first paralyzed, and then the muscular fibres of the heart and of the vessels. In consequence of the vascular paralysis all the other functions languish, and the state of the circulatory system may be the true cause of death, in which respiration is first arrested, and immediately afterwards the heart. It has no action on the vagus, either excitant or paralyzing, even in toxic doses. It causes a fall in temperature by increased dispersion of heat, in consequence of the vaso-motor paralysis, and it is not a poison of the protoplasm. Under the influence of berberine blood remains for a longer time undecomposed, and yields oxygen with more difficulty. It relaxes the tissue of the spleen, and increases rather than diminishes the size of this organ. It increases the peristaltic action of the intestine, both by its direct local action and by its general action after it has been taken into the blood-current; and produces at first diarrhoea and then a condition resembling dysentery. Acid urine is secreted even in the herbivora (rabbits). At times it is albuminous, and contains granular epithelial casts. The kidneys are congested, and sometimes present the signs of inflammation. Most of these conclusions were already published by the author in 1881.—*The London Medical Record*, No. 136, October 15, 1886.

THE DETECTION OF BLOOD-CLOTS IN THE PRESENCE OF IRON RUST.

DANNENBERG has found a new crystalline substance, which he calls hâmidin, the formation of which, in a crust in which blood is suspected, he considers a proof positive of its presence. It is produced in the following manner:

Two, four, or six drops of strong solution of potassium hydrate are dropped upon the crust, and allowed to remain there an hour. When the crust has softened it is carefully transferred to a porcelain dish and washed. A few drops of ammonium sulphate are added and the whole gently warmed. After ten minutes water is added and the whole fil-

tered. The filtration proceeds slowly, but the first drops show by the method of Erdmann the new crystals. A drop of the filtrate is placed upon a slide and dried, and a little acetic acid added. If blood be present, a mass of brown, rhombic plates appear, with a clearer, lighter spot in the centre; they are thought by Dannenberg to be proof of the presence of blood.

Crystals of other shapes are formed, and of other substances, but they do not present the characteristic features of h  midin. This substance is formed from blood by diluting it with two parts water, adding chloride of iron, and, after removing supernatant fluid, adding to the sediment ammonium sulphate. Water is added and the whole filtered, and the crystals are found in the filtrate.—*Deutsche Medicinal Zeitung*, December 9, 1886.

As an example of the prompt detection and correction of an error, Dannenberg, in the *Pharmaceutische Centralhalle* of recent date, states that he has repeated his experiments in the light of adverse criticism made by Amthor in the *Chemiker-Zeitung*, and agrees with his critic that the crystals which he found are *not* peculiar to blood, but are those of sulphur formed from the ammonium sulphide.

The whole is an interesting example of a recognized error in science, and may serve as a caution to those who work in physiological chemistry.

THE MANAGEMENT OF SIMPLE CONSTIPATION.

The untoward consequences of constipation are always considerable and sometimes serious; and greater than the an  mia, the blood-poisoning, the headache, the nervousness, and the heart disorders which rise out of f  cal retention are the untoward consequences of ignorant and unskilful domestic management.

In the *Lancet* for January 1, 1887, SIR ANDREW CLARK formulates the following brief and concise rules for the management of simple constipation:

1. On first waking in the morning, and also on going to bed at night, sip slowly from a quarter to half a pint of water, cold or hot.
2. On rising, take a cold or tepid sponge-bath, followed by a brisk general towelling.
3. Clothe warmly and loosely; see that there is no constriction about the waist.
4. Take three simple but liberal meals daily; and, if desired, and it does not disagree, take also a slice of bread-and-butter and a cup of tea in the afternoon. When tea is used it should

not be hot or strong, or infused over five minutes. Avoid pickles, spices, curries, salted or otherwise preserved provisions, pies, pastry, cheese, jams, dried fruits, nuts, all coarse, hard, and indigestible foods taken with a view of moving the bowels, strong tea, and much hot liquid of any kind, with meals.

5. Walk at least half an hour twice daily.
6. Avoid sitting and working long in such a position as will compress or constrict the bowels.
7. Solicit the action of the bowels every day after breakfast, and be patient in soliciting. If you fail in procuring relief one day, wait until the following day, when you will renew the solicitation at the appointed time. And if you fail the second day, you may, continuing the daily solicitation, wait until the fourth day, when assistance should be taken. The simplest and best will be a small enema of equal parts of olive oil and water. The action of this injection will be greatly helped by taking it with the hips raised, and by previously anointing the anus and the lower part of the rectum with vaseline or with oil.
8. If by the use of all these means you fail in establishing the habit of daily or of alternate daily action of the bowels, it may be necessary to take artificial help. And your object in doing this is not to produce a very copious dejection, or to provoke several smaller actions; your object is to coax or persuade the bowels to act after the manner of nature by the production of a moderate more or less solid-formed discharge. Before having recourse to drugs, you may try, on waking in the morning, massage of the abdomen, practised from right to left along the course of the colon; and you may take at the two greater meals of the day a dessertspoonful or more of the best Lucca oil. It is rather a pleasant addition to potatoes or to green vegetables.
9. If the use of drugs is unavoidable, try the aloin pill. Take one half an hour before the last meal of the day, or just so much of one as will suffice to move the bowels in a natural way the next day after breakfast. If it should produce a very copious motion, or several small motions, the pill is not acting aright; only a fourth, or even less, should be taken for a dose. When the right dose has been found it may be taken daily, or on alternate days, until the habit of daily defecation is established. Then the dose of the pill should be slowly diminished, and eventually artificial help should be withdrawn. The aloin pill is thus composed: \mathcal{R} Aloin  , $\frac{1}{2}$ gr.; extr. nucis vom., $\frac{1}{2}$ gr.; ferri sulph., $\frac{1}{2}$ gr.; pulv. myrrh  , $\frac{1}{2}$ gr.; saponis, $\frac{1}{2}$ gr. Fiat pil.
1. If the f  ces are dry and hard,

and if there is no special weakness of the heart, half a grain of ipecacuanha may be added to each pill. Should the action of the pill be preceded by griping and the character of the action be unequal, half a grain of fresh extract of belladonna will probably remove these disadvantages. If the aloin pill gripes, provokes the discharge of much mucus, or otherwise disagrees, substitute the fluid extract of cascara sagrada, and take from 5 to 20 drops in an ounce of water either on retiring to bed or before dinner. And when neither aloin nor cascara agrees, you may succeed by taking before the mid-day meal 2 or 3 grains each of dried carbonate of sodium and powdered rhubarb.

The exact agent employed for the relief of constipation is of much less importance than its mode of operation. If, whatever the agent may be, it succeeds in producing after the manner of nature one moderate-formed stool, it may be, if necessary, continued indefinitely without fear of injurious effects.

HYDRASTINE.

In the root of *Hydrastis canadensis*, besides berbine, a second alkaloid, hydrastine, is known to occur. An investigation of it has yielded interesting results to MESSRS. FREUND and W. WILL (*Berichte*, xix. 2797). Hydrastine was found to be most conveniently obtained by exhausting the finely-powdered root with ether, dissolving the residue left on evaporation in hot alcohol, and filtering; on cooling, the hydrastine crystallizes out almost pure. Analysis of the base and of an iodo-methyl compound confirmed the formula $C_{22}H_{23}NO_6$. Upon oxidation by means of potassium permanganate or dilute nitric acid, the base split up, a crystalline acid separating, which proved to be identical with opianic acid. From the filtrate a crystalline base was separated, melting at $115^{\circ} C.$, and very soluble in ether, alcohol, and chloroform, which so closely resembled cotarine, the base yielded together with opianic acid by the oxidation of narcotine, that it might have been considered identical had not an analysis shown that its composition was different. This resemblance of hydrastine to narcotine, from which it differs in its empirical formula only in containing one atom of oxygen less, was increased by the fact that the base resulting from its decomposition forms a crystalline hydride corresponding to hydrocotarine. It has been alleged that the root also contains two other alkaloids, to which the name of

"xanthopucine" and "canadine" have been given; but the authors failed to detect any other base than berberine and hydrastine. They separated, however, a crystalline neutral substance, apparently a kind of lactone, which, when treated with nitric acid, formed a crystalline nitrogen compound; this is to be the subject of further examination.—*The Pharmaceutical Journal and Transactions*, November 27, 1886.

HYPNOTIC PROPERTIES OF BOLDO-GLUCINE.

DR. RENÉ JURANVILLE, of Paris, has published as a graduation thesis an account of some experiments and observations on boldo-glucine, an aromatic substance of the nature of a glucoside, obtained by M. Chapoteaut from the leaves of the *Pneumus boldus*, or *Boldo fragrans*, a plant belonging to the *Mominiaceæ*, which has from time immemorial been employed by the natives of Bolivia, Chili, and Peru in hepatic diseases. The boldo-glucine used M. Juranville is not the same substance as boldine, which is an alkaloid existing in very small quantity in the leaves, and which was isolated in 1874 by MM. Cl. Verne and Bourgoin. The observations were directed to the hypnotic action of the glucoside, and were conducted on both animals and human subjects. Dogs were sent to sleep by intravenous injections of boldo-glucine, in quantities of from two to seven grammes. Observations were taken and curves constructed, showing that during the sleep produced the cardiac beats increased in rapidity, while the amplitude of the pulsations diminished; the arterial pressure was not affected. M. Juranville also gathered from his observations that anæmia of the brain was produced. His therapeutic researches were conducted on insane patients, the doses given being from 22.5 grains to 2 drachms, the substance being enclosed in gelatin-capsules or introduced by means of enemata. It was not found easy to administer it in the form of draughts on account of their powerful odor. It gave rise to no disagreeable symptoms, and, indeed, appeared to stimulate the appetite and the digestive functions. The hypnotic effect was very definite, ten patients on whom it was tried being all sent to sleep, and in some cases their hallucinations being removed; the effect was not, however, permanent, the sleeplessness and hallucinations returning on the cessation of the treatment. M. Juranville concludes that though boldo is not a perfect hypnotic, it is likely to prove valuable in cases

of neurotic or maniacal insomnia when other drugs have been tried without effect. Further study of its action is, of course, required before any very decided opinion as to its efficacy can be expressed.—*The Lancet*, October 16, 1886.

THE ACTION OF THE COMMON ALKALINE METALS AND EARTHS.

Potassium, sodium, lithium, calcium, and magnesium form the three following pharmacological groups, according to their action in mammals. The action of these agents has been investigated by CURCI (*Annali di Chem. e di Farm.*, June, 1886) with the following results : 1. The salts of potassium,—muscular agents, at first stimulant, then paralyzing. 2. The salts of sodium and lithium,—nerve agents, causing convulsions. 3. The salts of calcium and magnesium,—paralyzing nerve agents. However, while they manifest these three principal types of action on the nervous and the muscular systems, they have an almost identical action on the heart and circulation. They all at first cause increase of the blood-pressure, with slowing and strengthening of the pulse, and then lowering of the blood-pressure, with quickening and weakening of the pulse, and finally paralysis of the heart. Dr. Curci finds that when the medulla oblongata, and therefore the vaso-motor centre, is destroyed, potassium, sodium, lithium, and calcium produce increased blood-pressure, with slowing and strengthening of the pulse. Magnesium has no such effect. The first four, therefore, have a peripheral, magnesium a central, action. When the peripheral vaso-motor system is paralyzed by curare, sodium, calcium, and magnesium do not increase the blood-pressure, or but very slightly; while potassium and lithium, as in the normal state, markedly increase the pressure and render the pulse slower and stronger. Sodium, magnesium, and calcium therefore act on the peripheral vaso-motor nerves; while potassium and lithium act on the muscular fibre of the heart and blood-vessels. Potassium in mammals acts more rapidly and energetically on the vessel and heart muscular fibre than on the voluntary striated fibre; but, speaking generally, it acts on all voluntary and involuntary muscles, while it has no direct or manifest action on the nervous system. In the Batrachia, on the contrary, potassium acts first on the nervous centres and then on the peripheral nerves; afterwards on the voluntary muscles, and, lastly, on the heart. This is probably due to the low temperature of the

blood in batrachians. Curci finds that when frogs and toads are kept in hot water until their temperature equals that of a mammal, potassium acts in the same way as in warm-blooded animals. In this experiment, many times repeated, the heart was arrested before the complete abolition of reflex and voluntary movement. The excitability of the myocardium is exhausted before that of the striated muscles. In batrachians, therefore, at a low temperature the nerve-tissue is more sensitive than the cardiac muscle to the action of potassium; while at a high temperature this is reversed, and the heart becomes more sensitive than the nerves, just as in mammals.—*London Med. Record*, October 15, 1886.

URETHAN AND ITS ANTICONVULSIVE ACTION.

In the *Vratch*, Nos. 31 and 32, 1886, PROFESSOR VASILY VON ANREP, of Kharkov, publishes an important paper embodying the results of his extensive experimental researches on the action of urethan on the nervous system in frogs, rabbits, dogs, and pigeons (*London Medical Record*, December 15, 1886).

General phenomena of urethan-poisoning are almost identical and constant in all the animals named. First symptoms induced by the drug are a more or less intense general excitement, and quickening of the breathing and cardiac action. The period of excitement lasts always a relatively short time, but is the shorter the larger is the dose given. It is followed either by a complete recovery, or by a second period, which is characterized by immobility, failure of reflex action, retardation of breathing, decrease of the temperature, and a more or less deep sleep, the intensity and duration of which symptoms vary according to the dose and individuality of the animal experimented upon. In young dogs the hypnotic action of urethan seems to be stronger than in the older ones. When the dose is very large (fatal), a third and last period of the poisoning takes place; it is marked by a further retardation of respiration, absolute unconsciousness, absence of reflexes, enormous fall of the temperature, and weakened and retarded cardiac action. This period is very prolonged, and invariably leads to death from asphyxia. The fatal dose for a frog is as large as 0.4 gramme; for a rabbit 7 grammes per kilogramme of the animal's weight; for a dog, 5 grammes per kilogramme. Therefore, urethan possesses

but relatively slight toxic properties. Meanwhile, its action on the nervous system is very pronounced even when the drug is administered in comparatively small doses.

Reflex Action.—In frogs, small doses (0.03 to 0.1 gramme) are inactive; moderate doses (0.15 to 0.2 gramme) markedly lower the reflex action; large doses (0.25 to 0.35 gramme) not only decrease the latter but also lower irritability of the peripheral endings of motor nerves. The failure of reflexes always precedes the change in irritability of the nerve-endings, takes place not earlier than about half an hour after the poisoning (that is, only when the hypnotic influence of the drug is in full action), and disappears with the animal's awakening from narcosis. After large doses, a full prostration ensues in half to one and a half hours; it depends solely upon paralysis of the spinal cord. In warm-blooded animals, a short period of increased reflex action is observed, and only subsequently (after large doses) a decrease of the latter follows.

Sleep.—An average hypnotic dose for a dog and rabbit is 0.5 gramme per kilogramme. Easily excitable nervous dogs require considerably larger doses than the phlegmatic. After a 5- to 8-gramme dose, the animal falls asleep within twenty to forty minutes. The duration of sleep varies from several hours to two or three days. After awakening, general weakness, unsteady movements, and loss of appetite are observed. After a 10-gramme dose, the weakness lasts more than for twenty-four hours. Sensibility is more or less lowered for a short while before, during, and for one to ten hours after sleep.

Temperature.—A pronounced antipyretic action of urethan (which was first pointed out by Dr. Coze, and certainly deserves every attention of practitioners) is pretty constant. The fall of the (normal) temperature commences soon after the animal's falling asleep, may reach (according to the dose used) from 1° to 4° C., and last from two to six hours, to rapidly disappear after awakening. Fatal doses give rise to an enormous fall of the temperature (reminding only of cases of curare-poisoning). Thus, in a rabbit of five hundred and thirty grammes in weight, poisoned by 3½ grammes of urethan, the temperature within four hours fell from the original 39.7° to 32.8° C., to descend as low as 26° C. by the end of twenty-four hours (death ensuing on the fourth day).

Psychomotor centres, as examined in dogs, show a considerable and prolonged (several

hours) decrease of faradic excitability under the influence of hypnotic doses of urethan. Small doses of the drug produce only a short and slight increase of the irritability.

Anti-convulsive Action.—In view of a pronounced action of urethan on the spinal cord, Professor Anrep undertook a special series of experiments to study its relation to various convulsive poisons, such as strychnine, picrotoxicine, nicotine, and resorcin. In frogs, urethan may arrest or prevent convulsions caused by strychnine, but cannot either bring recovery or even delay the animal's death; on the contrary, its large doses accelerate death from strychnine (since both of the drugs kill by inducing paralysis of the central nervous system). It is otherwise in regard to dogs, rabbits, and warm-blooded animals generally, in which death in the case of strychnine-poisoning is very often caused by asphyxia, in consequence of tetanic contractions of the diaphragm and thoracic muscles. When the animal has been poisoned by a moderate dose of strychnine, an early internal administration of a few grammes of urethan pretty surely prevents, or at least considerably soothes, convulsions. A repeated administration of large doses of urethan may save the animal poisoned by a relatively small fatal dose of strychnine. In cases of poisoning by very large doses of the latter drug, urethan only arrests convulsions and postpones death. The same may be stated as regards the relation of urethan to picrotoxicine, nicotine, and resorcin. In other words, urethan possesses an anti-convulsive action, and may be usefully administered in cases of intoxication by convulsive poisons, as well as in diseases associated with convulsions. In this regard urethan occupies a higher stand than chloral, since, being as effective as the latter, it is free from any dangerous action on the organs of respiration and circulation. Judging from his experiment on dogs, Professor Anrep thinks that the doses of 8 to 12 grammes for an adult man may be given without fearing any dangerous or unpleasant accessory effects. At all events, in cases of poisoning, any good may be expected only from such large doses, since the smaller ones (3 grammes) would only give rise to a rather intense initial excitement. The most convenient mode of the administration of urethan in large doses is that through the rectum. The ingestion of large doses produces gastric disturbances.

LANTANINE.

Lantanine is an alkaloid discovered by M. Negrete, and extracted from *Yerba sagrada* of the family of verbenas. M. BUIZA has observed that, like quinine, this alkaloid had some action on the circulation. It slows the nutrition, and at the same time lowers the temperature. The most delicate stomachs tolerate lantanine. Intermittent fevers that prove refractory to quinine have yielded to the influence of 2 grammes (30 grs.) of lantanine. In order to produce antipyretic effects in febrile conditions the dose employed is from 1 to 2 grammes in twenty-four hours, given in pills of 10 centigrammes ($7\frac{1}{2}$ grs.). In intermittent fevers the drug is administered immediately after the paroxysm. Ninety-five times out of a hundred a further paroxysm will not appear. The tincture of lantana cannot be employed owing to its intense bitterness, which cannot be masked by syrup or wine.—*The Lancet*, October 16, 1886.

GUAIAECUM AS AN EMMENAGOGUE.

In the *Birmingham Medical Review* for January, 1887, SIR JAMES SAWYER states that he has given guaiacum in a large number of cases, and regards the drug as an active remedy in promoting the menstrual secretion in a large proportion of cases of amenorrhœa. It appears most efficient, when given alone, in those cases in which the cause of the amenorrhœa is obscure; that is, in those cases in which there is no obvious spanæmic deterioration to which the menstrual deficiency is referable. He gives 10 grains of the powdered resin of guaiacum, stirred in a wineglassful of milk, every morning before breakfast. The remedy may thus be given safely for some weeks. In a few instances it has been found to be necessary to suspend temporarily the administration of the drug, on account of the production of a little abdominal pain and purging.

In some cases of dysmenorrhœa guaiacum has been found to possess considerable curative efficacy. In those cases of dysmenorrhœa in which we can find no vice producing menstrual obstruction of a mechanical nature, and in which there are no inflammatory or plethoric signs, the ammoniate tincture of guaiacum is a reliable remedy when given during the painful period. From half a drachm to a drachm may be given as dose in a wine-glassful of water every two or three hours until the pain is relieved.

PHOSPHATIC DIABETES.

At a recent meeting of the Medical Society of London, as reported in the *Lancet* for January 15, 1887, DR. RALFE introduced to the notice of the Society a patient suffering from phosphatic diabetes, and read particulars of twelve others. These he arranged in groups according to the classification of Professor Teissier, who first gave a systematic account of the affection. Group 1. Excessive elimination of phosphoric acid associated with nervous derangements; three cases. Group 2. Excessive elimination of phosphoric acid associated with phthisis; three cases. Group 3. Excessive elimination of phosphoric acid alternating with saccharine diabetes; three cases. Group 4. Excessive elimination of phosphoric acid running a distinct course, like saccharine diabetes, only without the sugar; five cases. All the cases, with the exception of two, were young adult males. The symptoms common to all were great emaciation, aching rheumatic pains in loins and pelvic regions, dry, harsh skin, with tendency to boils, and ravenous appetite; in some cases cataract develops. In the majority there was polyuria; in others the urine was normal in quantity, with a high specific gravity. The urea was increased in some cases slightly, in others to a greater extent; but the great feature of all the cases was the very considerable and constant elimination of phosphoric acid, with or without increase of the other constituents of the urine,—a feature which distinguishes it from insipid diabetes on the one hand and azoturia on the other, with both of which it has been improperly confounded. The pathology, Dr. Ralfe thinks, depends not so much on increased metabolism of nervous matter as on defective nutrition, so that the tissues are not able to utilize the phosphorus brought to them, and consequently a greater amount passes through the system daily. In those cases in which an excessive excretion of phosphoric acid replaces saccharine diabetes, it is probable that acids like oxy-butyric-glycollic, etc., formed by imperfect oxidation of the sugar, dissolve out the earthy phosphates from the tissues, which appear in excess in the urine. As regards the prognosis in these cases, it is most unfavorable in the first two groups; country air, massage, cod-liver oil, may for a time do good, but the patients rapidly fall back, and either are carried off by some acute attack proving fatal in their exhausted condition, or drift on into phthisis or into diabetes mellitus. The prognosis of the last two groups is much more favorable: of the three cases recorded in

Group 3, two got completely well; the third still suffers from saccharine diabetes, but it remains in a mild form.

MR. W. A. MEREDITH and MR. A. P. GOULD made some remarks.

In reply to Mr. B. Carter, DR. RALFE said that there was only the volumetric method, uranium nitrate being the agent used to precipitate the phosphates. Care must be taken that a specimen of the mixed twenty-four hours' urine is used to estimate the daily discharge of phosphates.

Reviews.

VON ZIEMSEN'S HANDBOOK OF GENERAL THERAPEUTICS. Vol. V.

New York: William Wood & Co., 1886.

The fifth volume of this encyclopædia masquerading under the name of a handbook is occupied by two elaborate treatises. The first of these is written by Prof. F. Rusch, of Berlin, and translated by Dr. Noble Smith. It considers general orthopædics and massage. Of its two hundred and seventy-five pages over two hundred are occupied with a discussion of the causes, symptoms, and diagnosis and treatment of deformities. Its general characteristics are similar to those of previous articles in the book, thorough, Germanic; it must not only be of value to every general practitioner who essays to treat diseases which are discussed in these pages, but also to the well-read specialist. As instances that its author is more familiar with German habits than with those of the Anglo-Saxon, may be mentioned the statement that the bicycle, or, as it is called in the book, the two-wheeled velocipede, is preferable to the horse, because "its rider does not run the danger of considerable injury from a fall." Certainly the Anglo-Saxon two-wheeler is a more dangerous beast than is its quadruped rival.

The second half of the book before us is occupied by a treatise on "Hydrotherapeutics," by Dr. W. Winternitz. The translator, F. W. Elsner, dates his preface from Melbourne, and, if his work is to be judged as a specimen of antipodal English, we fear that noble Anglo-Saxon is in serious danger of mortal injury at the hands of our distant *confrères*. He says, "In the pious endeavor to render the translation as nearly as possible in the author's own style, the translator fears that he has now and again offended against the laws of idiom

slightly, but this he hopes will be excused him, as that can hardly be considered a translation which will be practically a rewritten work, if elaborate syntax is to be the fixed rule without departure."

The spirit of this sentence is a most aggravating one. The translator who sacrifices his native tongue to the barbarities of Teutonic involution deserves death. If he cannot properly translate German into good English, he should go to either a German or an English schoolmaster; or, if unwilling to do this, should altogether abstain from translating. The sentence we have quoted, however, evinces urgent need of English study. The adjective "slightly" ought to be in front of its verb offended; "but this he hopes will be excused him," ought to read, "for this he hopes he will be excused," since as it now stands the passive verb is made to govern the pronoun him like an active transitive verb. Again, the change of tense from the present to the future time in the next to the last clause of the sentence is atrocious. "Can be" should be followed by is, not "will be." On the whole, we commend this sentence to professors in grammar as affording an excellent exercise to their students in pointing out errors of construction. We have no doubt, as stated by Dr. Elsner, that the German of Dr. Winternitz on "Hydrotherapeutics" is extraordinary, but we are inclined to think that the translation is still more marvellous.

William Wood & Co. should have employed some one to have translated, or at least to have edited, the translation. We have wrestled with some of the sentences almost as long as Jacob wrestled with the angel, but with far less success. To drop figures, in a word, the English of this translation is often understood with difficulty. When to this is superadded the prolixity, which probably characterized the original essay, the apparent total absence on the part of the author of any knowledge of work done outside of Germany, and the indefiniteness of many of the statements, it is plain that the essay is not an attractive one. The most valuable part of it to the general reader, according to our thinking, is the account of the different methods of applying cold and hot water generally and locally. For this and for other things to be gleaned from it the treatise is worthy of study, but it still remains for some one of practised literary skill and of scientific and practical knowledge of the subject, to write for the profession a concise, readable account of "Hydrotherapeutics."

THE NATIONAL DISPENSATORY. By Alfred Stillé, M.D., LL.D., and John M. Maisch, Phar.D. Fourth Edition.

Philadelphia: Henry C. Lea's Son & Co., 1886.

The National Dispensatory is too well known by the reading medical and pharmaceutical public to require elaborate review at this date. Its virtues and its faults, its successes and shortcomings, are matters of common repute. On the appearance of a new edition it is simply the province of the reviewer to indicate how far the book has been rewritten and how thoroughly it has been revised. Examination shows that in the present edition the changes have consisted not in a thorough overgoing of the various articles, but are chiefly in revision of the references to the British Pharmacopœia, and in the addition of certain articles to the end of the book as a sort of appendix. This so-called addenda occupies about thirty-five pages, and consists of articles upon Antipyrin, Cocaine Hydrochlorate, Cascara Sagrada, Fabiana, Francisca, Gymnocladus, Hydroquinone, Hypnone, Iodol, Jacaranda, Lanolin, Menthol, Phormium, Sulphophenol, Thallin, and Urethan, and a few other unimportant matters. The fact that these articles are placed at the end of the book and not inserted at their proper position, indicates that the present is a reprint from old plates, which have been so little altered as not to modify their paging. Comparison of the pages of the two editions confirms this suspicion. Of a large number of pages looked at in the fourth edition, each commences with exactly the same syllable as does the corresponding page of the third edition.

Correspondence.

LONDON.

(From our Special Correspondent.)

You know that with an Englishman the first subject of conversation is the weather. You smile at this insular peculiarity of ours, but I trust you do not regard it as altogether unreasonable. If you were in London at this moment you would pity and sympathize with us, for you would understand how it is that the weather is always at the tip of our tongues. Cold, damp, and dirt are an unpleasant combination of miseries to live in. Our hardy Anglo-Saxon race cannot be charged with being afraid of cold, and, for the matter of that, a certain degree of damp, but we do re-

sent dirt, even when it comes in the shape of disinfectant smoke and soot. We are living in a nearly constant fog,—not constant in the degree which you have vividly realized from Dickens or Taine, but a fog that is always here to some depth, and which thickens every few days into the classical pea-soup atmosphere of these authors. Every one knows the strange adventures of the street on these occasions from the graphic pictures drawn by master-hands, but has any writer looked inside the walls to tell of the scenes within? Up the lanes and courts of this vast city, in the few square feet of a room which a whole family calls its home, what of the child ill of measles, the puerperal mother, or the father with emphysema and dilated heart? Fresh air is out of the question. Ventilation is a mockery with the oxygen choked out of the atmosphere by soot and the other foul products of the chimney. Warmth is the first consideration: windows are fastened up and stopped and stuffed. The fire is the only friend, if a fire can be afforded. What wonder if with all this the death-rate of London rise from eighteen to twenty-two in a week? Even in hospitals you may see, these days of fog, patients dying under your very eyes from asphyxia. We have to leech them, to open a vein, and to dose them with ether, alcohol, and carbonate of ammonia, in order to keep the blood moving in the heart and lungs, and the corpuscles fairly charged with oxygen. These are but poor make-shifts,—but feeble attempts to cope with an evil of our own making. Can nothing be done on a larger scale—on a scale worthy of modern applied science—to rid us of this demon, fog? We have had a smoke exhibition, a smoke abatement association, smokeless stoves, smokeless coals; but one after another they seem to have had their day and disappeared, leaving us in still deeper darkness. For myself, I cannot see how matters can do other than grow steadily worse as long as London increases in extent on its present principles of construction. Fog appears to increase with the area of chimneys in an increasing ratio. Some of us would positively try to stay the further growth of the metropolis! This is a hopeless proposal. But could we not insist, if we had anything like an intelligent municipal government, on the adoption of other means of heating and lighting? Why should every room be a smoke-centre? Does any one attempt to deny that before the present century ends we shall have discarded coal in a great measure in the kitchen? May we not

hope that heat will shortly be supplied on a large scale to great blocks of habitations in such a city as this? How much longer shall we tolerate the blazing gas in sitting-rooms and bedrooms, with its foul, noxious, if invisible, products, whilst electricity is ready at hand? I trust this reference to a question which so nearly concerns us on this side may not be considered out of place in an American journal of therapeutics. More than half of the science and art of treatment consists in prophylaxis, and the proportion is ever growing. Let the great country where towns and cities are being daily founded take careful note of our experience.

It is satisfactory to turn from what might and ought to be—but has not been—done in the direction of preserving health and life to what has been accomplished during the year which is just closing in the way of treatment among us. Short though the record of visible progress in therapeutics may be in England, there can be no question about the steady and substantial, if somewhat slow, advance of all the departments of medicine that contribute to sound scientific treatment. It could not well be otherwise. The enthusiasm manifest among us just now is extraordinary; and if I had to deplore in my last letter to you that so few of our younger men appear to have taken to practical therapeutics, I will not deny that they are doing their best to lay a sound foundation of a future science of healing. Unquestionably this activity is part of a wave that has reached us from Germany, whence have come so many of our methods and so much of the exact physiology and pathology on which our own investigations are based. But, apart from these less definite forms of progress, this country may be proud to chronicle at the end of the year the share it has taken in the improvements in the art of healing.

First among these is unquestionably the recent development of the surgery of the brain. During the past year a number of cases of cerebral tumor and other morbid conditions of the intracranial region have been subjected to surgical interference. Hardly a week now passes but one hears of some operation on the brain surpassing its predecessors in magnitude, and, as far as I have learned, performed with success. Hitherto the cerebrum has been the part of the brain attacked; but the other day Mr. Horsley, of University College and the Hospital for Epilepsy, who has performed most of these operations with us, removed a tumor

from the cerebellum. It has not been my good fortune to be present at any of these operations of Mr. Horsley's; but I am assured that nothing could be more remarkable than the freedom with which he treats the parts,—freedom, I mean, which comes of knowledge, confidence, and skill. The bone is very freely removed, and when the brain is reached one is startled by the size of the portion that may be taken away, including, of course, the morbid mass. In every instance the urgent symptoms have been relieved,—the continuous series of epileptic fits or the profound coma in which the patient may have been lying for many months. In another aspect these operations on the cerebral substance are of rare interest to us. The exact relations of the excised portions of brain are carefully ascertained, and thus not only is the regional diagnosis, made before the operation, rigidly tested, but an opportunity is afforded of studying, after the operation, the physiological effects of removal of a definite area of the convolutions. Manifestly both these series of results must be interpreted with great caution at present; the effects of inflammatory stimulation and of general intracranial pressure, on the one hand, being liable to be confounded with those of direct irritation or with paralysis from loss of brain-substance on the other hand. By and by, as cases multiply, we shall be able to eliminate these sources of fallacy. One may well envy Dr. Hughlings Jackson and Dr. Ferrier, our true pioneers of cerebral surgery, the satisfaction with which they watch the results of operations in such cases, several of which have been under their own care.

In my letter which you published in August I referred to the incursions that our surgeons had been making into another region which until quite recent times was considered to belong peculiarly to the physician. I mean the lungs. We do not appear to have gone much farther in this particular direction the last few months. No doubt the surgical treatment of diseases of the chest in general, including especially pleurisy and its multiform results, has become more definitely systematized. Here, also, as in the case of the brain, operation is constantly affording us an opportunity of testing our diagnosis, and thus of advancing our knowledge of the nature and signs of diseases of the chest, along with their treatment. I have heard nothing, so far, of the routine treatment of cavernous phthisis by intrapulmonary injections, such as I see reported in some of your American journals.

We are anxious to hear more of this system, which sounds to some of us "too good to be true." Another system of treatment of lung-disease which has just been introduced to our notice by our French colleagues is Bergeon's method of gaseous enemata. No doubt before this letter reaches the light you will have heard of the apparatus or seen it at work. I need hardly tell you that the system is being received here with great caution, not to say criticism. At first sight nothing could look less likely to be successful, or even, if useful, to commend itself in general practice, than the treatment of phthisis by the injection of a large quantity of gas into the bowel! This objection, which I suggest on the score of unpleasantness, is, however, greatly diminished when one finds that the gaseous enemata can easily be self-administered beneath the bed-clothes. When we turn to the rationale of the method we find a number of difficulties in connection with it which must be removed before we can accept this as a scientific mode of treatment. When carbonic acid gas is pumped through a bottle of Eaux-Bonnes water it carries with it a load of sulphuretted hydrogen. We are told that if this compound be introduced into the rectum by means of an ordinary enema-pipe, it is absorbed by the bowel, passes by the veins to the lungs, and is there excreted, the sulphur compounds acting as germicides in the pulmonary tissues. We are told that by this method cases of phthisis have been greatly benefited,—indeed cured,—not to speak of bronchitis, bronchiectasis, and spasmodic asthma. You will gather at once that a great deal is assumed in the account given by the authors with respect to the action of sulphuretted hydrogen introduced into the bowel. How do we know that the gas follows the route indicated, once it has entered the blood? Is it not altered in the liver, through which it must pass? One point seems clear,—that there is no odor of sulphides in the air of expiration. May the sulphur not escape by the skin, or by the kidneys, as sulphates? The practical criticism that I hear directed against the method is even more destructive. A few isolated cases of phthisis temporarily improving in a hospital, whilst being treated as special patients under a new system, are valueless as evidence. To draw any definite conclusion from instances of nervous asthma is manifestly out of the question. Still, it would be unfair to prejudge the method, and I am not going entirely by theory. It has been on its trial at the Victoria Park Hospital for Diseases of the Chest for a couple of

months, and, although this is much too short a time for judgment to be pronounced for or against a line of treatment, there is nothing encouraging in the reports that reach me.

In the department of medicinal therapeutics the greatest gain of which we have been enabled to avail ourselves has no doubt been in the allied classes of disinfectants, antiseptics, and antipyretics. We frankly confess that we have to thank our German colleagues for most of the novelties of these kinds, although Sir Joseph Lister and his pupils deserve great credit for their advocacy of corrosive sublimate in the treatment of wounds. Antipyrin has won and still holds its ground among us as a powerful antipyretic, but it must be confessed to be far inferior in activity to antifebrine, which is now being fairly tried. The weak point of these drugs is unquestionably the transient character of their febrifuge effects, as compared with quinine and the other old-fashioned methods of securing defervescence. Sparteine, which was so highly vaunted in Paris, seems to have disappointed English expectations. The diuretic effect of calomel—a remedy which has never ceased to be prescribed in dropsies by our older physicians—has been revived with success. These are but a few brief annotations of our recent experience of certain "new" remedies, which are doubtless attracting attention with yourselves.

You will hardly believe me when I tell you in as many words that one of the greatest of our London hospitals is suffering seriously at the hands of our brethren in the States. Yet I am speaking the truth. Free trade with your vast grain-growing country has reduced the value of corn to less than fifty per cent. of what it fetched a few years ago. Foreign meat is sold in Liverpool at threepence or fourpence a pound. This may sound like the millennium for the hungry mouths of our artisans, though the blessing to them is a doubtful one when its full economical effect is carefully weighed, but it is simple ruin to our farmers and land-owners. Now, one of our large land-owners is Guy's Hospital, which is mainly dependent on agricultural prosperity. The income of Guy's has fallen within a short time to as nearly as possible one-half. Guy's is a beggar for the first time in its history, which extends back more than a hundred years, and includes the glorious roll of names like those of Astley Cooper, Hodgkin, Richard Bright, Addison, not to speak of Gull, Pavy, Moxon, Fagge, Wilks, and others who have belonged to our own generation.

Yesterday a public appeal was made for one hundred thousand pounds to put the treasury of Guy's on its feet again, and, from the rate at which the money flowed in, I have little doubt the required sum will soon be raised. This is only an incident in the mendicant history of most of our London hospitals, which are, with a few exceptions, entirely dependent on charity. I trust you have more satisfactory arrangements in the States. There must be a serious waste of money in managing the crowd of institutions for medical and surgical relief which London maintains. Ought we not at once to face the problem, complex and heavy though it may be, of putting all our hospitals under the management of a single public board, and supporting them by public rates?

Before these lines have reached you we shall have entered on the jubilee year of our gracious sovereign lady, Queen Victoria, a name as dear with you as it is to us. English Medicine has just cause to celebrate the beneficent rule of the past fifty years, which has enabled it to grow from what was little more than a refined empiricism to the well-founded science which it is to-day. In this respect Medicine is but one of the many sciences that have flourished during the Victoria period. As a profession we owe to our queen far more than the general prosperity that comes of national advancement, of peace, and of social purity. It is our pride that Queen Victoria takes a special interest in us. Besides the many acts of personal favor which she has shown to those who have been near her and her family in their hours of illness, she has repeatedly given public evidence of her interest in our institutions for the study and application of medical science. Last summer she emerged from her comparative seclusion to lay the foundation-stone of the new building on the Thames Embankment, which ratifies the union for examination purposes of the Royal Colleges of Physicians and Surgeons. It is sincerely to be hoped that by the end of the jubilee year something like order will have replaced the confusion which overspreads all our regulations and arrangements for medical education and graduation in England at the present time. I also hope that a place will be found for Medicine in the great Imperial Institute which has been planned to commemorate the closeness of the federal tie that now binds our colonies and dependencies to the mother-country and their veneration for our common sovereign.

STIGMATA MAIDIS IN GONORRHŒA.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—I think if E. Stuver, M.Sc., M.D., of Rawlins, Wyoming Territory, will look on page 280 of the *Medical Record* for September 6, 1884, he will find an article on Stigmata Maidis, recommending its use in gonorrhœa. I have used the fluid extract a number of times since reading the above-mentioned article, but have been disappointed at the result. It will act very well as a diuretic in cases requiring such an agent, but I don't think it has any more beneficial influence over the course of gonorrhœa than other agents of the same class.

Respectfully,

J. W. TRISLER, M.D.

URBANA, ILLINOIS, December 20, 1886.

Notes and Queries.

A CASE OF BELLADONNA-POISONING.

We have received the following communication from a physician who, for evident reasons, desires to remain nameless.

"In July, 1882, I was to attend Mrs. J. E., æt. 30, American, and mother of six or seven children. Had given birth to twins at a previous labor. Mother and family were healthy. They were very poor, living from hand to mouth, and she had had her children at very short intervals. I found her in labor, and diagnosticated twins. In due time one child was born, large and well nourished. After waiting half an hour, and there being no indications of pains, contrary to my custom I thought I would administer ergot. My pocket-case was on a table near by, and as my hands were soiled, I asked an attendant to take a bottle out of my case, indicating the one. My attention was then called to the woman in labor (I had in the mean time been using friction of the fundus to induce contraction), and I then told the attendant to turn out half a teaspoonful. She used a tin spoon nearly twice as large as an ordinary teaspoon, and administered the dose. After waiting about twenty to thirty minutes, I told the attendant to give a teaspoonful dose, as there was no evidence of returning pains. About that time Mrs. E. complained of dryness of the throat, but I took no notice of it, as it is not an uncommon symptom. I did note that her pulse was more frequent, and she said that she could not see well, so in order to hurry things up I gave her a little more,—about a quarter of a

teaspoonful ; in fact, about all that I had. The patient wanted to be moved, and I took her under the armpits and drew her up in bed. She remarked that something had come away, and sure enough on examination I found the child's head born, but could not detect any evidence of uterine contraction. The mother now became quite delirious and talked incoherently and could not see the light. For the first time it dawned on me that there had been a mistake, and on looking at my medicine-case I discovered that the ergot bottle was in it and full, and the bottle containing fluid extract of belladonna was empty and on the table. My feelings can be better imagined than described. I immediately administered half a teaspoonful of the sulphate of zinc, and prepared a good half-grain of morph. sulph. By the time I had given the morphine (hypodermically) she had vomited with the aid of a finger in the fauces. In the mean time I had tied the cord and disposed of the child. Symptoms were becoming more alarming every moment ; pulse very rapid, and a marked redness began to show very plainly. This deepened until she looked like a lobster.

"I soon again repeated the dose of morphine. It seemed certain that I was to have a corpse on my hands, and I determined to push the morphine until I got some physiological evidence of its effect, so that within an hour I should think I gave a grain and a half. Patient was nearly unconscious, and no response could be got from her. Pupils were dilated to the utmost.

"I was anxious to get away, and told the husband that I would drive home and would be back directly. I said something about 'puerperal mania,' brought about by bearing children too fast, and that I did not think it possible his wife could recover.

"I went home in a bad state of mind, believing that I had killed the woman. In about two hours I returned, fully expecting to find a corpse. But no, the respirations were a little slower ; pupils about the same. Gave another dose of morphine, and waited about an hour for effects, and fancied that other signs looked more favorable. Respiration was certainly improving, and the iris began to show itself. I gave still another hypodermic of morphine and left her, returning in about two hours. Her condition was then much improved ; the iris was about half visible, and respiration quite natural. Again I repeated the morphine, and after waiting some time left her some morphine powders, to be taken

every four hours. I felt encouraged, but dreaded that some sequel might occur that would carry the woman off, but I felt confident that I had been on the right track so far as the antidote was concerned.

"The woman made a good recovery, and was subsequently killed by the cars.

"I have much regretted that I did not keep a more accurate record of symptoms, but really regarded the case as hopeless from the time my mistake was discovered. I am sure that she took at least f3iiss fluid extract of belladonna, and that from the time of taking the first dose up to the emesis was about an hour and a half. Probably she vomited a little of the last dose (one-quarter of a teaspoonful), but the emesis was not thorough.

"I am also sure that I gave her not less than *three grains of morphine* in about *six hours*, hypodermically, and the larger part of this was given during the first two hours.

"Two facts I am sure that I have impressed on my mind. One is that belladonna relaxes all of the structures opposing the expulsion of the foetus, and another is that morphine is an antidote to belladonna in large doses. I have also learned in my experience with morphine narcosis that atropin is very efficient, and indeed I depend mainly on it in such cases.

"D. G. P."

TREATMENT OF WHOOPING-COUGH.

Concerning Dr. Kohlmetz's treatment of whooping-cough, I would add that I have given quinine for several years with the most beneficial results, but with this difference in the manner of administration, viz., that I have used it with finely-powdered white sugar placed dry on the tongue every two or three hours. Under this treatment all my cases have invariably improved rapidly, and, when followed up properly, were cured in a short time.

GEO. A. HETHERINGTON, M.D.

SAINT JOHN, N. B., December 31, 1886.

THE INEQUALITY OF THE PUPILS IN VARIOUS DISEASES.

DR. PASTERNAKSKI, who has been working in Professor Chudnovski's clinic in St. Petersburg, has published in the *Vratch* an account of a number of observations he has been making on the inequality of the pupils in various diseases, thus carrying out a suggestion made by his chief in a work on the methods of examining medical patients. pub-

lished in 1883, in which he expressed an opinion that careful examination of the pupils would lead to interesting results. Dr. Pasternatski examined a number of methods which have been proposed, but did not find any of them suitable for his purpose, and ultimately a much simpler plan, suggested by M. Follin, was adopted. This consists in bringing a catheter gauge-card close to the eye, and comparing the size of the pupil with the apertures in the card. By this means the size of the pupil in millimetres can be ascertained with a degree of accuracy sufficient for the purpose. It is important to make the observations in the shade, for the difference, when there is any, between the diameters of the pupils increases as the light is diminished. The best method of conducting the examination is to close the eye which is not being observed, for this causes a slight increase in the diameter of the pupil of the latter, as was indeed remarked by Hippocrates. It was found, for example, in a case in which this was tested, that when both eyes (being in the shade) were fixed on an object at a distance, the diameter of the right pupil was $5\frac{1}{3}$ mm., and that of the left 6 mm.; when, however, the eye not under examination was covered up, the diameters increased to 6 mm. and $6\frac{2}{3}$ mm. respectively. As to the diseases in which inequality of pupils has been observed, Dr. Pasternatski quotes a number of cases mentioned by continental physicians; also one of aneurism shown by Professor Gairdner to the Edinburgh Medical Society; as well as two reported by Professor Finlayson in the *Lancet* of January 3, 1885, in both of which aneurisms were found at the necropsy. His own observations gave the percentage of cases in which inequality was found in various diseases as follows: Croupous pneumonia, 85; heart-diseases and aortic aneurisms, 61; pleurisy, 52; chronic catarrhal pneumonia, 38; acute articular rheumatism, 25; catarrh of the respiratory passages, 25; scurvy, 16; typhus, 16; recurrent typhus (relapsing fever), 15; abdominal typhus (enteric fever), 13. Inequality of pupils was also found in half the cases of catarrhal and hepatic jaundice and renal colic. The largest percentage occurred in croupous pneumonia, and study of the cases showed that the position and stage of development of the disease has a remarkable effect upon the pupils. At the very commencement the pupil on the same side as the affected lungs, as a rule, larger than the other. The difference generally increases with the lung inflammation, reaching its height on the third,

fourth, or fifth day; before the crisis the difference decreases, sometimes even disappearing. Afterwards, during the stage of resolution, a difference is again manifest, the pupil on the affected side being now contracted. Not only do the pupils in pneumonia differ in size, but also in sensibility to light. Speaking generally, the author's observations lead him to believe that inequality of pupils is most frequently met with in those internal diseases which not only affect the system generally, but which, like pneumonia, pleurisy, and hepatic and renal colic, are definitely localized as well. It is also very usual in heart-diseases and aneurism, but comparatively rare in scurvy and infectious diseases, such as typhus, and when it does occur in these it is generally consequent on some complication.—*Lancet*, January 15, 1887.

TEST-PAPERS FOR RECOGNIZING ALBUMEN.

These are two papers, one of which has been soaked in concentrated solution of citric acid, the other in solutio hydrarg. potassica, which is potass. iod., 3.32 parts; sublimate, 1.35 parts; acetic acid, 20 parts; aquæ destill., 40 parts.

The paper is dried and cut in slips.

Both papers are dipped into the suspected urine, which is shaken, the paper forming a thread in the test-tube. If albumen is present, cloudiness or a precipitate forms.

This test is very delicate, reacting with .001 per cent. of albumen.

It precipitates also uric acid, mucin, and alkaloids. Uric acid dissolves on the application of heat; alkaloids are dissolved by alcohol.—*Wiener Zeitschrift für Apotheker Vereins*, December 10, 1886.

GUACHACATA.

M. CRESCENCIO GARCIA proposes to substitute for quassia, gentian, quinine, etc., the flowers of a Mexican plant commonly called guachacata, and promises further information about the botany of the plant. Garcia prepares a bitter elixir by extracting first with alcohol and then with water and mixing the products; this is done because the plant contains two chief bitter principles, one soluble in alcohol, the other in water. The formula runs thus: guachacata flowers, 30 grammes; rectified spirits of wine, 300 grammes; sweet orange peel, 15 grammes. Macerate for a

week or a fortnight in sunlight; express; treat the residue with a little boiling water; express; mix the liquids.—*London Medical Record*, December 15, 1886.

PASTEUR'S INOCULATIONS IN RUSSIA.

PETERMANN, of Moscow, has established an inoculation station at Moscow in connection with the military hospital, and reports the following results: in three months 115 patients have been treated, of whom 87 were bitten by rabid dogs, 18 by rabid wolves, 5 by rabid horses, 4 by rabid cats, 1 by a rabid hog. As regards the portion of the body most exposed, 11 were bitten in the face, the remainder on the limbs and trunk. 55 were bitten in August, 31 in September, when apparently rabies is most common. The preparations of spinal cords used in inoculation varied from those which had been in course of development thirteen days to those which had been two days in preparing. Two of the 115 patients died, one who was inoculated fourteen days after the bite was received from a dog, and one who was bitten by a wolf, and inoculated eight days afterwards. The same method of treatment at Odessa was applied to 103 persons. In 36 cases the dog was probably rabid when the bite was inflicted; the others were doubtful on this point. The mortality was 7, greater than in Paris, but the virus used was weaker. Thirty to sixty-two days was the period of incubation in the fatal cases. The Society of Russian Physicians at St. Petersburg has given the matter much warm discussion, and an earnest effort is being made to test the accuracy of all reports and the genuineness of the rabies to which the patients are thought to have been exposed.—*Deutsche Medicinal Zeitung*, No. 96.

AN ANTIDOTE FOR ARSENIC AND ACONITE.

In a recent number of the *Indian Statesman* there appears a communication from SYED WALAYET ALI KHAN, of Patna, Benga, on a specific antidote for poisoning by arsenic and aconite. It is described as being the bark of the common goolar-tree, generally known to Europeans as the Indian fig. It is administered in doses of from 10 to 12 drachms, ground fine, and mixed with water. In severe cases it may be necessary to repeat it at short intervals three or four times, but it is said never to fail. It has been found success-

ful, according to the author of this statement, in every case in which it has been tried. We have consulted Dymock's "Vegetable Materia Medica of Western India," Waring's "Bibliotheca Therapeutica," and other works, but can find no reference to its use for this purpose. It seems strange that it should be an antidote both for arsenic and aconite, as these drugs do not produce the same symptoms, and are not allied physiologically. The matter requires further investigation, and we must admit that we are at present sceptical as to its value.—*Lancet*, January 15, 1887.

A VALUABLE METRIC TABLE.

The Popular Science News, in its recent issue, gives a table, unlike others of the kind, in giving the equivalents of both the common and metric system together, and is worth preserving for reference, as follows:

Length.		
Unit of measurement.	Approximate equivalent.	Accurate equivalent.
1 inch.....	$\frac{1}{2}$ cubic centimetres.....	2.539
1 centimetre ($\frac{1}{2}$ inch).....	0.4 inch.....	0.393
1 yard.....	1 metre.....	0.914
1 metre (39 37 inches).....	1 yard.....	1.093
1 foot.....	30 centimetres.....	30.479
1 kilometre (1000 metres).....	$\frac{1}{2}$ mile.....	0.621
1 mile.....	$\frac{1}{2}$ kilometres.....	1.609
Weight.		
1 gramme.....	$\frac{1}{15}$ grains.....	15.432
1 grain.....	0.064 gramme.....	0.064
1 kilogramme (1000 grammes).....	$\frac{1}{2}$ pounds, avoirdupois.....	2.204
1 pound, avoirdupois.....	$\frac{1}{2}$ kilogramme.....	0.453
1 ounce, avoirdupois (437 $\frac{1}{2}$ grains).....	28 $\frac{1}{2}$ grammes.....	28.349
1 ounce, troy or apothecary (480 grains).....	31 grammes.....	31.103
Bulk.		
1 cubic centimetre.....	0.06 cubic inch.....	0.061

The calculation necessary to convert one system of measurements into the other is very simple. For example, suppose we are directed to use 175 grammes of chlorate of potassium, for making oxygen, how much is it in ounces? We see by the table that one ounce equals 31 grammes; divide 175 by this, and we have 5.6, the required number of ounces. If we wish to measure 53 cubic centimetres of any liquid, $53 \div 29.5$; the number of cubic centimetres in one fluid-ounce = 1.8 fluidounces, the required amount. Conversely, suppose we have a quantity of some chemical weighing three-quarters of a

pound, and wish to find the metric equivalent. As one pound is equal to .453 kilogramme, three-quarters of a pound will be equal to three-quarters of that weight, or .33975 of a kilogramme; or, as one kilogramme equals 1000 grammes, three-quarters of a pound will equal 339.75 grammes.

The approximate figures in the second column are sufficiently accurate for ordinary work, while those in the third column are correct to the third decimal place. The table was purposely made simple, and only those weights and only those measures are given which are in constant use. In this connection may be added a set of rules, which, if committed to memory, would render the conversion of one system of weights into the other very simple indeed.

1. To convert troy grains into centigrammes, multiply by 6.

2. To convert centigrammes into troy grains, divide by 6.

3. To convert troy grains into milligrammes, multiply by 60.

4. To convert milligrammes into troy grains, divide by 60.

5. To convert troy grains into grammes, or minims into fluidgrammes, divide by 15.

6. To convert grammes into grains, or fluidgrammes into minims, multiply by 15.

7. To convert drachms into grammes, or fluidrachms into fluidgrammes, multiply by 4.

8. To convert grammes into drachms, or fluidgrammes into fluidrachms, divide by 4.

SUBLIMATE-GLYCERIN-GELATIN.

The *Zeitschrift für Apotheker Vereins* speaks of the success which has often occurred in veterinary practice with this combination, and describes its preparation as follows:

Common gelatin is treated with one per cent. sublimate solution twelve hours; the gelatin is then melted, and ten per cent. of glycerin added.

TOXIC EFFECTS OF ONE-ONE-HUNDREDTH OF A GRAIN OF SULPHATE OF DUBOISINE.

At a recent meeting of the Leeds and West Riding Medico-Chirurgical Society Dr. CHADWICK related a case where this amount of the drug, instilled for examination of a

senile cataract, produced a state of delirium lasting many hours, leaving the patient totally unconscious of what had occurred. There was great muscular weakness, and many strange actions were performed. It was suggested that the susceptibility to this drug reached its maximum in old age, and that the similarity between the symptoms and those of senile atrophy, popularly known as "softening of the brain," might suggest that its action was by causing spasm of the cerebral arterioles, and might indicate a possible liability to that form of pathological change. Dr. Major said the symptoms closely resembled those he had noticed in a medical friend, who took for experimental purposes a large dose of hyoscyamine, being characterized by strange antics, with curious unreasonableness. He attributed much of the effect to delusions of vision.—*The Lancet*, January 8, 1887.

WOOD-FIBRE AS A DRESSING.

DR. PORT, of the German army, recommends in the *Deutschen Militär-Artzlichen Zeitschrift* wood-fibres as an excellent base for dressings. This material is not only of an absorbing nature and free from germs, but possesses also greater elasticity than the cotton-fibres, and does not roll up when used. The elder-tree is most suitable for the purpose. The wood-fibres, before being used, are to be immersed into a solution of corrosive sublimate, expressed, wrapped up in mull, and then applied.

PILOCARPINE IN DATURA STRAMONIUM POISONING.

According to the Paris correspondent of the *British Medical Journal* (January 15, 1887), DR. ROTH (Nagy Bajour, Hungary) was summoned to a little girl aged 4, whom he found quite unconscious. The pupils were dilated, the face and the rest of the body were swollen as in dropsy, and covered with a rash resembling that of scarlatina. The little patient was uneasy and restless, and ground her teeth. Pulse 146, slight and weak; respirations 40; temperature 39° Cent. (102.2° Fahr.). Her bowels had not been opened, nor had she passed urine since the commencement of the attack. A local medical man had prescribed 15 centigrammes of antimony; but her father, who was a chemist, being persuaded that this would do no good, gave her a solution of sulphate of copper. She vom-

ited a large quantity of the fruit of the datura stramonium. Dr. Roth, remembering how Professor Purjeck had cured a case of atropine-poisoning by means of subcutaneous injections of pilocarpine, administered half a centigramme of that drug in twelve hours. This produced neither salivation nor perspiration, and there was no improvement. After a centigramme had been injected, however, the rash and the swelling began to subside. A quarter of an hour later another centigramme was injected, and the child's condition improved still more. The injections were continued, and at six o'clock the pupils had become almost normal. Pulse 120; temperature 39.7° Cent. (102.9° Fahr.). The patient spoke with ease, and said she felt hungry. An hour later, as there was still no perspiration, another half-centigramme was injected. Salivation and perspiration ensued, and rapid recovery followed. Altogether, five grammes and a half were administered. Dr. Roth considers that this dose was necessary to neutralize the poison.

NATHTHOL IN EXCESSIVE SWEATING OF EXTREMITIES AND THE AXILLA.

The *Journal de Médecine et de Chirurgie* recommends against excessive sweating of extremities or of the axillary region the following lotion :

Naphthol, 5 parts;
Glycerin, 10 parts;
Starch, 100 parts.

After having applied this lotion, the parts are to be dusted with the following powder :

Powdered naphthol, 2 parts;
Powdered starch, 100 parts.

In excessive sweating of the feet little cotton-balls saturated with the powder may be inserted between the toes.

AMMONIA APPLICATIONS IN MALIGNANT PUSTULE.

DR. LEONIDAS AVENDAÑO, of Peru, who has previously written (*vide The Lancet*, January 9, 1886) in favor of the local treatment of anthrax by ammonia, now publishes in a Lima medical journal an account of a recent case of undoubted malignant pustule in which he successfully adopted this treatment. The patient was a married woman, aged 34, who, two days after being stung by some insect in the forearm, began to experience the symp-

toms of acute inflammation in the spot. Thinking an ordinary boil was forming, she applied poultices. The next day, when seen by the writer, the pulse was 105, there was a great deal of oedema and redness about the arm, and there was a papule, which was blackish at the centre and surmounted with a circle of vesicles. The etiology, the rapid development, and the local symptoms all pointed to the malignant nature of the case. A crucial incision was made, and a brush saturated with the ordinary solution of ammonia applied to the cut surfaces. An acetate of ammonia and aconite mixture was ordered, and in a few days the patient was well. Dr. Avendaño thinks that other caustics which have been employed in anthrax—as nitric acid, chloride of antimony, and Vienna paste—only partially and incompletely destroy the bacillus anthracis, but that ammonia has a much more powerful effect. This makes the fifth case in which he has seen remarkably successful results follow its employment.—*The Lancet*, October 2, 1886.

BROMIDE OF ETHYL IN CONJUNCTION WITH CHLOROFORM.

At the meeting of the Baltimore Academy of Medicine held November 2, 1886, Dr. J. J. CHISHOLM stated that he has now employed the bromide of ethyl, in conjunction with chloroform, as an anæsthetic. His method is to anæsthetize the patient first with bromide of ethyl, and then to keep up the anæsthesia with chloroform. The advantage claimed by him for this method is that he accomplishes the desired result much more quickly than when chloroform is used alone.

TANGENA VENENIFERA.

Tangena venenifera, the ordeal-bean of Madagascar, has been made the subject of physiological experiment by QUINQUAUD. He finds that applied to frogs, the drug suspends voluntary motions, heightens the reflex excitability, and causes clonic and tonic convulsions. Later, symptoms of paralysis set in, though the excitability of the muscular apparatus and of the peripheral motor nerves remains intact at first, but ultimately the system appears as if affected by a curare poison. In dogs, vomiting, diarrhoea, and tenesmus precede the convulsions. The muscular power, however, remains normal until death ensues. Tangena fruit quickens the respiration, then slows it. The frequency of the pulse is increased for a

brief period, and then diminished; the blood-pressure is at first raised and then depressed, so that apparently the circulation and respiration are simultaneously affected, the action of the heart outlasting that of respiration. Quinquaud has given an extract of the seed in doses of 1 to $1\frac{1}{2}$ grains in various diseases, and has come to the conclusion that it can be used in paralytic affections of a toxic nature, atony of the intestines, and in tremor. In some cases of urinary incontinence, distinct improvement followed the use of the drug. The indications for suspension of the treatment are the presence of headache, vomiting, or a sensation of weakness.—*Provincial Medical Journal*, November 1, 1886.

A LIQUID VESICANT.

BIDET recommends the following: Cantharides is treated with chloroform in a distillation apparatus, so that the quantity of chloroform shall remain by redistillation a litre in the following mixture:

Cantharides, 1000 parts;
Chloroform, q. s.;
Wax, 125 parts.

—*Pharmaceutische Post*, October 30, 1886.

COLOMBINE.

M. Roux has observed the effect of pure colombine on fowls, the only animals which he has been able to get to take the medicine by way of the mouth. The symptoms produced by the ingestion of the poison were those that are associated with fatty degeneration of the liver and destruction of its working elements. Colombine irritates the intestinal tube, causing increased secretion from the gastric, intestinal, and biliary surfaces. The occurrence of these serious symptoms makes it necessary that the administration of the drug to human beings should always be in the form of small doses. The daily dose to commence with should not exceed one centigramme ($\frac{1}{100}$ gr.) of the alkaloid, and the powders of columba are to be preferred to the less certain alcoholic and ethereal liquid extracts.—*The Lancet*, October 2, 1886.

ANOTHER CORN CURE.

MOBILITY OF THE HEART.

DR. M. M. SHERSHEVSKI publishes in the *Vrach* a paper on the mobility or displaceability of the heart. The fact that the heart's position is liable to slight changes, according to the position of the body, has been recognized by Bamberger, Gerhardt, Luschka, and other observers, but they have none of them formulated the conditions under which it takes place. Dr. Shershevski gives details of the examination of forty persons, all of them free from cardiac and pulmonary affections, in whom he noted accurately the position of the heart's boundaries in the upright dorsal, left lateral, and right lateral positions. The chief mobility was towards the left side, but the heart was often quite perceptibly displaced to the right, as well as downwards and even backwards. The chief conditions under which this occurred were youth, nervous states, and freedom of the vessels from signs of sclerosis. Displacement backwards was found in nearly half the cases, and this shows that the heart ought to be examined in the upright posture. The writer specially remarks on this when the examination is made as a prelude to the administration of chloroform, whereas, as a rule, the stethoscope is applied when the patient is lying down and in a very agitated frame of mind, which latter condition always renders the organ more easily displaced; and the diminished diameter due to this may lead to erroneous conclusions if the measurements be not previously taken in an upright position. This has reference chiefly to young persons. In the case of subjects over sixty years of age, and of much younger persons whose arterial system had already begun to show signs of degeneration, there was little or no displacement produced in any position.—*The Lancet*, November 20, 1886.

THE NON-CONTAGIOUSNESS OF PULMONARY TUBERCULOSIS.*

By THOS. J. MAYS, M.D., PHILADELPHIA, PA.

WE are probably safe in asserting that the majority of the members of the medical profession are impressed with the belief that pulmonary consumption is a contagious disease. If this current opinion is true, it becomes one of the gravest questions, both in domestic and public hygiene, to define the proper relation between the consumptive pa-

tient and his surroundings. Therefore, fully appreciating the difficulties which envelop this problem, and holding the highest regard for the intelligent minds with whom we are compelled to take issue, we shall offer no other apology than the importance of the subject for making it the topic of this paper; with the express avowal, however, that this is not undertaken for the mere purpose of entering the arena of controversy, but from a conviction that the belief in the contagiousness of the disease is erroneous, and with a sincere desire to add something which, perchance, may be of value in placing this much-disputed question on a more solid basis than it has heretofore occupied.

Viewed from the broad stand-point of evo-

* Read before the Philadelphia County Medical Society February 23, 1887.

lution, as this question naturally must be, it will appear that all the infectious diseases are the result of a living union and interaction of unlike though not too highly specialized cells; or, to be more specific, these diseases are the products of grafting one cell on another,—a process identical with that of grafting practised in the vegetable world, and with skin-grafting frequently resorted to in the human subject,—and their intensity depends on the activity of the reproductive power with which these cells are endowed. This reproductiveness is common to every living cell in the animal body, but varies widely in different cells, being most active in those which are least differentiated, or, in other words, in those which retain the nearest approach to the original cell-type. In the lower stages of life all the cells in an organism are equally endowed with the power of reproduction, and any indifferent segment is capable of reproducing the whole animal. Thus, protozoa multiply by spontaneous fission, and the original organism resolves into a number of new individuals like the parent. But in the evolutionary changes of animal life the cells of some tissues undergo a greater modification than those of others, and those which diverge most from the original type become the least reproductive, while those which undergo no, or very little, change remain the most reproductive. In this higher stage of life the process of reproduction is carried on by a specialized tissue,—the ovary and testis,—the cells of which only retain the power of reproducing the whole animal, while in the cells of the other tissues, although they are still capable of reproducing themselves, this power is lost. The form-elements of the body consist of epithelial tissues, tissues of the connective substance, the muscular, and nervous tissues, and of all these the nervous tissue has the highest and the epithelial tissue the lowest organization. Gegenbaur says that epithelium represents both phylogenetically and ontogenetically the oldest and most primitive form of cellular tissue.

Now, reproduction itself is generally regarded as a very complicated process, and one for the performance of which highly specialized organs are considered essential; but on examination it will be found that both the sperm-cell and the germ-cell originate in the epithelial layer, which, as we have seen, is the simplest and most unspecialized tissue in the body. Hence, from a biological point of view, it is an extremely simple process. In relation to this subject Herbert Spencer

("Biology," vol. i. p. 220) says, "The organs for preparing sperm-cells and germ-cells have none of the specialty of structure which might be looked for did sperm-cells and germ-cells need endowing with properties essentially unlike those of all other organic agents. On the contrary, these reproductive centres proceed from tissues that are characterized by their low organization. In plants, for example, it is not appendages that have acquired considerable structure which produce the fructifying particles: these arise at the extremities of the axes, where the degree of structure is the least. The embryo-cells are formed in the undifferentiated part of the cambium layer; the pollen-grains are found at the little-differentiated extremities of the stamens, and both are homologous with simple epithelium-cells. Among many inferior animals, devoid of special reproductive organs, such as the *hydra*, the ova and spermatozoa originate in the layer of indifferent tissue that lies between the endoderm and the ectoderm,—that is, they consist of portions of the least specialized substance. And in the higher animals these same generative agents appear to be merely modified epithelium-cells,—cells not remarkable for their complexity of structure, but rather for their simplicity."

But this is not all that concerns us here; for, in accordance with a well-known physiological law, organic cells manifest an elective affinity for one another during the process of fertilization, which is weakest when the sperm-cell and the germ-cell possess too much sameness, and strongest when these cells originate from the same tissue in different individuals of the same species. This is well shown in the vegetable world. Nearly all plants are hermaphrodites,—that is, they are so situated that it is possible for the ovules of each flower to be fertilized by pollen from the same flower; yet practically this does not occur, for Mr. Darwin has demonstrated that either the ovules and pollen of the same plant do not ripen simultaneously, or that other obstacles arise which prevent fertilization in this direct way, and that the most vigorous vegetation is produced when fertilization takes place between different plants. The same law of cell affinity also exists in the highest organisms.

That which is of the greatest interest to us at present in these biological phenomena is (a) that the cells of every tissue in the animal body possess the power of reproducing themselves; (b) that the power of reproducing the whole individual is shared only by the cells of the epithelial tissue; and (c) that the process

of reproduction is most active between the slightly differentiated cells of the same tissue not in the same, but in different individuals. And we shall find that these deductions are as applicable to pathological as they are to physiological processes, for disease is propagated in the same manner as health is.

When under proper conditions a germ which has been modified by disease is grafted on a healthy germ, disease-germs will be produced, and the number of disease-germs thus produced will depend on the facility with which both germs reproduce themselves; and from what has been said it is evident that disease-germs will be most abundant when the epithelial tissues are involved, and least abundant when they originate in the nervous or muscular tissues, while those coming from the white or connective tissues occupy an intermediate position in this respect.

We have now arrived at a point where we are enabled to define the term contagion. Broadly, it may be stated that all infectious diseases are either contagious or inoculable, and that both of the latter terms represent processes which differ in degree only and not in kind. It is essential to both that their respective germs should find lodgment in the circulation before the disease is transmitted from one individual to another, and whether a germ is contagious or not depends on the facility with which it gains admission to and multiplies itself in the tissues for which it has an affinity; or, in other words, if a germ has the power of entering the circulation through the coverings of the body, it is a contagious germ; but when this is not the case, and it must be introduced by means of artificial force, then the germ is not contagious, but inoculable. Now, the facility with which a germ enters the blood is in a great measure owing to its reproductive activity outside of the blood. A germ which rapidly multiplies, and which disseminates a great number of contagious germs throughout the atmosphere, will expose the recipient body to a greater number of such germs in a given time, and hence will be more communicable than that germ which is devoid of these properties, or possesses them in a less degree. That the numerical element plays a very important part in the process of contagion and of inoculation is very evident from the examples which Darwin gives us in illustration of the analogous process of sexual genesis. He says,* "This view of the importance of

the quantity of formative matter seems probable from the following considerations: There is no reason to suspect that the spermatozoa or pollen-grains of the same individual animal or plant differ from each other; yet Quatrefages has shown in the case of the *Teredo*, as did formerly Prevost and Dumas with other animals, that more than one spermatozoon is requisite to fertilize an ovule. This has likewise been clearly proved by Newport, who adds the important fact, established by numerous experiments, that, when a very small number of spermatozoa are applied to the ova of Batrachians, they are only partially impregnated, and the embryo is never fully developed. The first step, however, towards development, namely, the partial segmentation of the yolk, does occur to a greater or less extent, but is never completed up to granulation. The rate of the segmentation is likewise determined by the number of the spermatozoa. With respect to plants, nearly the same results were obtained by Köreuter and Gartner. This last observer found that even thirty grains did not fertilize a single seed; but when forty grains were applied to the stigma, a few seeds of small size were formed. Naudin made the following interesting experiments: A flower was fertilized by three grains, and succeeded perfectly; twelve flowers were fertilized by two grains, and seventeen flowers by a single grain, and of these one flower alone in each lot perfected its seed, and it deserves especial notice that the plants produced by these two seeds never attained their proper dimensions, and bore flowers of remarkably small size."

Taking into consideration, then, what has been said concerning the fertility of the epithelial tissues and the comparative infertility of the other tissues, it will be obvious on *a priori* grounds that those diseases which are located in the former are contagious only, while those lodged in the latter are inoculable but not contagious; and we shall see with what remarkable uniformity this induction obtains among the infectious diseases when they are classified in accordance with this idea. Thus, the principal infectious diseases of the epithelial tissues are—

Smallpox,	} First group.
Cow-pox,	
Measles,	
Scarlatina,	
Diphtheria,	
Typhoid fever,	
Gonorrhœa,	
Erysipelas.	

* Animals and Plants under Domestication, vol. ii. pages 435 and 436.

Those of the connective tissues are—

Sarcoma,	} Second group.
Carcinoma, (?)	
Tubercle,	
Syphilis.	

It will be observed that the contagiousness of the first group of the infectious diseases as above given is directly related to the severity of the cutaneous eruption; and this is a practical confirmation of the above-made deduction that the degree of contagiousness is due to the number of contagium particles thrown off from the skin and diffused throughout the atmosphere. Smallpox produces the most extensive as well as the most intensive disturbance in the skin of any of the eruptive fevers, in all probability emits the greatest number of germs, and is admittedly the most contagious. Next in order of contagiousness comes measles, the cutaneous disturbance of which is no more marked than that of scarlatina; and yet it is said to be more contagious, because the eruption of measles is chiefly confined to the skin, while the most intense lesions of scarlatina are concentrated in the throat, from whence the contagium particles are less readily diffused than they are from the free external surface of the body. Then, again, it is a well-known fact that in many cases of measles the cuticle is cast off in a finer state of division than it is in scarlatina, and this of itself renders the epithelial germ of the former disease more diffusible. Owing to the violence of the process of diphtheria, this disease, although not accompanied by any well-defined skin-affection, ranks next to scarlatina in point of contagiousness.

In regard to the contagiousness of typhoid fever, in the sense in which the former term is used here, there can be but one opinion, but for the reason which has already been given, viz., that diseases of the internal surfaces are less contagious than those of the external surfaces, its contagious influence is rather limited. Occasionally, however, in cases where the dejecta are unduly exposed to a dry and warm atmosphere, or where they are confined in an improperly ventilated cess-pool, the contagium particles diffuse so rapidly in the first instance, and accumulate and enter dwellings through drainage-pipes in such quantities in the second, that they become an undoubted source of contagion.

Gonorrhœa is the only one of the infectious diseases of the epithelial tissues in the above list which is not contagious; due, undoubtedly, to the fact that only a small surface area is

involved, and that the lesion is confined to a tubal cavity with a narrow opening on the outside, all of which forbid a multiplication and dissemination of germs in sufficient quantity to give rise to the danger of infection through contagion.

Erysipelas is essentially a skin-disease, and, as a rule, is non-contagious. Generally it is limited to a comparatively small area, and hence is not so liable to contaminate the surrounding atmosphere, and so become contagious; yet when the disease involves a large extent of surface, and at the same time exists in an aggravated form, or becomes epidemic, it certainly throws off a sufficient number of gemmules to become contagious, as is well attested by many clinical facts.

From what has already been said it follows that the infectious diseases of the second group cannot be contagious, because they are principally located beneath the cutaneous and mucous surfaces of the body. It is well ascertained that, with the probable exception of carcinoma, all of them originate from or inhabit the connective tissue. Thus sarcoma and syphilis invade the subcutaneous, the sub-mucous, or subserous fibrous tissue, or the connective tissue of other organs; while tubercle infects the lymphatic system, which is but a modified form of the same tissue. There can be no doubt that the stroma of cancer is of connective-tissue origin, but whether its cells come from the same source, or are of epithelial origin, is a disputed point among our best histologists. This is immaterial so far as the question is here concerned, for these growths, like those of sarcoma, syphilis, and tubercle, are almost exclusively confined below the bodily surfaces, and hence have not sufficient communication with the atmosphere to become contagious. All these diseases are, however, infectious, for they have been communicated by means of inoculation. They all manifest a strong tendency towards auto-infection,—i.e., the original cells multiply and distribute their germs throughout the body by means of the blood and lymphatic circulation. In this manner sarcoma and carcinoma disseminate themselves and become very malignant in their course, the rapidity of the dissemination depending somewhat on the softness or succulency of the original growth. In the same way syphilis and tubercle are capable of contaminating the white or connective tissue of the principal organs of the body from one infectious centre.

Thus when the infectious diseases are

viewed from a biological stand-point we find that they naturally divide themselves into two classes,—viz., the contagious diseases, or those which are readily communicated; and the non-contagious or inoculable diseases, or those which are not readily communicated. If, in consonance with this idea, the same method of reasoning were carried further, it could also be shown that growths occurring in muscle and nerve, which are the most highly differentiated tissues in the body, possess no infectious or communicable property whatever; but we think that from this side of the question enough evidence has been brought forward to show that pulmonary tuberculosis both from its nature and relation is entirely devoid of contagion, and that it is no more communicable than cancer, syphilis, or any of the diseases with which it has the closest histological affinity.

After having said this much on the deductive side of the non-contagious nature of pulmonary tuberculosis, we will endeavor to ascertain the trend of the evidence on its inductive side. This evidence divides itself naturally into that which has been gleaned from experiment, and into that which has been derived from clinical experience. The first consists in inoculating and feeding animals with, and compelling them to inhale, tuberculous material; and the second consists in tracing the influence which tuberculous patients exert on their living surroundings through ordinary intercourse.

In regard to the experimental evidence, it may as a general rule be stated that artificial tuberculosis can be induced in the lower animals most readily by inoculation and least readily by feeding the poison, notwithstanding the facts that in numerous instances negative results are obtained by any method of introducing it; that many animals, like rabbits, guinea-pigs, etc., are more susceptible to its action than dogs, cats, etc.; and that it seems to be more communicable when introduced into the abdominal cavity than in the eyeball. The successful genesis of tubercle in this artificial way is, however, no more than one would be led to expect from a knowledge of its nature and of that of many kindred poisons, and is not the least evidence that they possess any contagious property; for abscess, gonorrhoea, malaria, etc., are communicated in the same manner, yet no one thinks of ascribing the power of contagion to these diseases.

While, then, there is no doubt as to the inoculability of pulmonary tubercle, it remains to be proven whether this disease is ever trans-

mitted between man and man, or between man and animals through atmospheric contagion. For obvious reasons clinical evidence is the only umpire to which we can appeal for a solution of this part of the question, and in order to bring this clearly into view we shall endeavor to compare the salient characteristics of those diseases, which are undoubtedly contagious, with those of pulmonary tuberculosis.

Exposure.—As a rule those who are most exposed to a contagious disease are most liable to it, while the opposite is true of pulmonary tuberculosis. Do the practitioners of medicine, and especially those who believe in the contagiousness of the disease, take the proper precautions against infection in this manner, or do their actions fail to confirm their professions? On this point Professor Lichtheim expressed himself in no uncertain tones before the Second Medical Congress of Germany, which met in Wiesbaden in 1883. Among other things he said that it must be admitted that there are many facts which contradict the contagious nature of pulmonary phthisis. Intercourse with consumptive people is not attended with danger. We hospital physicians spend much time among such people, and we have such confidence in the innocuousness of the disease that we do not hesitate to mix healthy persons with them in institutions devoted to its treatment, and we must confess that this procedure is practically unattended by any unfavorable results. He further stated that the mortality of the attendants in the principal hospitals for consumption was surprisingly low; and that he could, from investigation, confirm the belief that there is no relation between the increase of the number of phthisical patients at a health resort and the number of deaths from consumption occurring among the native inhabitants.

The statistics of the Brompton Hospital for Consumption in London, as collected by Drs. Williams and Humphreys, speak in the same emphatic manner against the contagiousness of pulmonary tuberculosis. This large institution shows that during a period of thirty-six years not a single clearly authenticated case of pulmonary consumption among all its attachés emanated from within its walls. During the thirty-six years there were twenty-nine physicians and assistant physicians connected with the hospital, and among these occurred a single case of phthisis, and he was tuberculous before he entered it. The rest were all well. Dr. Edwards was resident for

twenty-six years, yet he showed no sign of the disease. During that period there were employed one hundred and fifty clinical assistants. Of these eight died of consumption; but all, except one, were sufferers from the disease before they became connected with it, and in this one case there is doubt as to the origin of the trouble. Among the one hundred and one nurses, of which there is a health record, one is suffering from a slow form of the disease, which may have been contracted during her service at the hospital, although she is predisposed to consumption. She is an old employé, and able to attend to her duties efficiently most of her time. No more positive proof of the non-contagiousness of pulmonary phthisis could be gathered anywhere than is furnished by this large institution. Every one of the individuals associated with this hospital were almost constantly exposed to the disease, and still there is only a single case to which the least claim of contagion could be made, and this rests largely on suspicion.

These statistics in regard to the non-contagiousness of phthisis are strikingly confirmed by those which relate to the influence of the Consumption Hospital of Görbersdorf, in Germany, on the death-rate from phthisis among the inhabitants of that town. Dr. Brehmer, who has been in charge of that institution for twenty years,* says that since the year 1854 more than ten thousand consumptives resided in the Görbersdorf hospital, who walked the streets of the town daily and mingled with its inhabitants. The latter were, therefore, constantly respiring an atmosphere more or less laden with tubercle-bacilli emanating from the dried expectorations of these consumptive visitors; yet, in spite of these favorable conditions for contagion, the mortality statistics of the town show that prior to 1854 there were 10.07 annual deaths from consumption among its inhabitants, while from 1854 to 1880 there were only 5.0 deaths per year, or a death-rate somewhat less than one-half of what it was before the introduction of the hospital. These figures are especially interesting in view of the assertions frequently made that the healthful influence of mountain resorts is impaired by the infectiousness of the exhalations and expectorations coming from consumptive people who go there for the purpose of seeking relief, showing that such suspicions are more imaginary than well founded.

Then, again, it is common to find physicians, both in this country and in Europe, who are sufferers from consumption, and therefore compelled to spend most of their lives in the mountain resorts of their native countries, to labor hard among their many fellow-sufferers who constantly crowd these places, and yet they experience no inconvenience from their contact with these people, but, on the other hand, regain exceptionally good health.

Once more, not very long ago, Dr. J. Solis-Cohen, who has since become our honored President, said before this society that if any class of medical practitioners is more exposed to the virus of tubercle than another it is certainly the class to which he belongs, viz., the laryngologists. They are constantly operating on patients with tubercular ulceration of the throat, inhaling their breath and often their cough, and are continuously exposed to the evaporation of the sputum in the cuspadores of their offices, yet he was unaware of a solitary instance of infection brought about in this way.

Contagion between Husband and Wife.—In 1883 a committee, appointed by the British Medical Association, investigated the contagiousness of pulmonary phthisis by sending a printed circular asking the members of the profession throughout England whether they had observed any cases in which the disease was believed to have been communicated. The committee received ten hundred and seventy-eight answers. Of these, seven hundred and seventy-eight were negative, thirty-nine were doubtful, and two hundred and sixty-one were affirmative. Of the affirmative answers, one hundred and fifty-eight were cases where the communication of the disease was supposed to have taken place between husband and wife, or *vice versa*, eighty-one between members of the same family, and the remainder were principally cases between whom there was no blood connection.

On account of the large number of affirmative opinions, this report has been made to subserve the interests of those who believe in the contagiousness of phthisis. Evidently this is unfair, since the aim of the investigation was not to ascertain the number of absolutely well-demonstrated cases in which contagion was present or absent, for this would obviously have been next to an impossibility, but to collect the individual opinions of a large number of physicians as to whether they believed the disease contagious or not, and this resulted in seven hundred and seventy-

* Die Aetiologie der Chronischen Lungenschwindsucht, p. 18.

eight negative, and two hundred and sixty-one affirmative votes. Are we, therefore, justified in assuming that the two hundred and sixty-one opinions are of more weight than the seven hundred and seventy-eight negative ones, and thereby imply that the former only had the fortune or the misfortune to meet cases which originated through contagion, and that the latter had not? Is it not more probable that all of them witnessed cases around which hung a cloud of suspicion that they might be contagious, but that seven hundred and seventy-eight did not consider the proof strong enough to outweigh that which in their minds was in favor of other and more powerful influences in the production of the disease? Evidence of infection between married people is, we believe, much less common than it is generally believed to be. In our whole personal experience we can only recall a single instance where the wife may have contracted it in this way, although even in this case there is an incomplete family record, and the patient herself was a dress-maker and in all probability was predisposed to the disease. But were the fact of its communication established in any given case, it would still devolve upon the contagionists to prove that the virus was not introduced under very unusual conditions,—such as being inoculated through an abrasion of the skin or mucous membrane by intimate contact of one person with another.

As still further proof of the correctness of our view concerning the non-contagiousness of phthisis between husband and wife, we beg to call attention to a most admirable paper, entitled "Eine Statistische Studie als Beitrag zur Aetiologie der Lungenschwindsucht," contributed by Dr. Schnyder to Nos. 10, 11, and 12 of the *Correspondenzblatt für Schweizer Aerzte* for 1886. This contribution is based on three thousand four hundred and sixty-one cases of pulmonary phthisis, which were observed by its author while resident physician at the health resort of Weissenburg, in Germany. Of these cases, eight hundred and forty-four occurred among married people, but in four hundred and forty-five of them it was the husband only, and in three hundred and sixty-seven instances it was the wife only, while in thirty-two cases both husband and wife were affected. Now, it must be admitted by the most ardent contagionist that here existed the most favorable conditions for a propagation of the disease between husband and wife, or *vice versa*, through contagion; and the fact that eight hundred and twelve

of these cases escaped even a suspicion of contagion, shows clearly that the disease is not by any means readily communicated under extraordinary circumstances. But is it beyond doubt that the thirty-two cases originated through contagion? We think not, for, as Dr. Schnyder says, it is a notorious fact that, in spite of all entreaties and warnings, young people are often wedded while suffering from active lung-disease. He relates four such cases in his own experience in which both the bride and bridegroom came to Weissenburg, fresh from the matrimonial altar, to be treated for phthisis, from which they both suffered. But even letting those who are wedded while suffering from active phthisis out of the question, it cannot be denied that many young people of both sexes carry the hereditary taint of the disease in their constitution, which only awakes from its slumbering condition to assert its power when the many varied burdens and demands of family life begin to exhaust the vital resources.

Moreover, we have recently shown* that consumption makes its appearance in families which are perfectly free from all evidence of the disease. Proof based on two hundred cases of phthisis was there given, that the youngest members of families, provided either or both parents were the youngest members of their respective families, are especially predisposed to this disease. In view of this fact, it is of great importance to scrutinize the family record well before we jump at the conclusion that the disease must have been derived through contagion in the absence of a phthisical family history.

On the point of communicability between husband and wife, the late Dr. Flint, in his work "On Phthisis" (p. 420), says, "In my collection of cases (670), these five are all that I find in which there is room for the suspicion of the disease having been communicated from the husband to the wife, or the wife to the husband. By making inquiries of members of the medical profession, and searching periodicals, doubtless a considerable number of similar cases might be obtained. Collected in this way, however, they would not prove communicability. According to the law of chances, a disease of such frequent occurrence as phthisis would affect in succession a husband and wife, or *vice versa*, in a certain proportion of cases. Conceding

* "Some of the Causes of Pulmonary Consumption, viewed from a Darwinian Stand-point," *Medical News*, November 27, 1886.

that the histories of some of my cases are defective in information on this point, it is certain that the instances in which transmissibility may be suspected are not sufficient in number to be not allowed for as coincidences. It must, therefore, be concluded that the analysis of my cases does not furnish facts sufficient to render the communicability of phthisis probable."

Again, it is a well-known fact that phthisis may originate independently from a caseation centre located anywhere in the body outside of the lungs. Thus enlarged lymphatic glands of the neck, which so frequently follow dentition, or catarrhal affections of the mouth, may caseate at some inopportune time, and generate the specific virus which produces tubercle. Such glands are a standing menace to their possessor, and we have no doubt that they are the cause of at least some of the occult cases of tubercular phthisis. We have no doubt that pulmonary tuberculosis can arise from other infection centres in the body. Thus pyosalpinx, about which we have learned so much recently from Dr. Joseph Price, and from other members of this society, quite often goes on to caseation, and is said to be frequently accompanied, and probably followed, by tubercular involvement of the lung. How many such infection sources may originate spontaneously in the body as the legitimate product of ordinary catarrhal inflammation?

Infectiousness of the tubercle-bacilli, or tubercle-virus, diffused throughout the atmosphere.—In the deductive or biological part of this paper we have given sufficient reason to show that one of the essential requirements in a contagious disease is the property of contaminating the surrounding atmosphere with an abundant crop of disease-germs. We also endeavored to give proof from this standpoint of the question that this is true of smallpox, and of all the active diseases of the external surface of the body, and that it is not true of sarcoma, tubercle, syphilis, or of any of the internal diseases of the body. We shall now inquire whether this harmonizes with the inductive or experimental evidence which can be collected on this point.

Ever since it has been believed that the specific virus of tubercle resides in the bacilli, efforts have been repeatedly made to demonstrate the presence of these organisms in the atmosphere; and while it is claimed that they are always present, they have at no time been shown to exist in sufficient quantities to give rise to the danger of infection.

Baumgarten,* to whom belongs the credit of being a co-discoverer of the bacillus tuberculosis, and who implicitly believes that this organism is the causative agent of pulmonary phthisis, says that he never knew of a single well-established case of phthisis which was acquired through respiring an atmosphere vitiated by the exhalation of consumptive people. And he further says that during the last ten years he made and had made in the Pathological Institute at Königsberg a large number of inoculation experiments on rabbits with tuberculous material, constantly keeping inoculated animals in the same cage with the non-inoculated, the latter thus being exposed to an atmosphere infected with bacilli; yet in no single instance was the tubercular poison conveyed from the inoculated to the non-inoculated animal.

Referring to the work of the two Italian experimenters, Celli and Guarnieri, who undertook to decide whether and under what circumstances a tuberculous person is liable to infect the surrounding atmosphere, Baumgarten describes the three series of experiments which these scientists made. In the first series they placed three ventilating devices, the inner surfaces of which were well covered with Koch's culture gelatin, at different elevations in the chamber of a consumptive patient. The air of the room was strained through these instruments for twelve nights in succession. Part of the gelatin at the end of this time was examined microscopically, and part was inoculated into the eye, the peritoneal cavity, and into the subcutaneous connective tissue of rabbits and of guinea-pigs.

The second series consisted in allowing a number of phthisical patients to respire for a long time into a reservoir which was well coated with Koch's culture gelatin, after which the gelatin was examined microscopically and inoculated into the eye, peritoneal cavity, and subcutaneous connective tissue of rabbits and of guinea-pigs.

In the third series they experimented with air which was aspirated through tubes containing tubercular sputum. The sputum was evaporated by heat, and the air thus exposed was forced through a tube containing sterilized blood-serum and Koch's gelatin. The experiments were continued for many hours, and in many instances were repeated. The culture media were then tested in the same manner as in the two former series,—viz.,

* *Berliner Klinische Wochenschrift*, 1884, p. 626.

by microscopic examination and by inoculation.

Every one of these experiments was followed by negative results. In no case did the microscope reveal a bacillus, nor was tuberculosis produced in any of the animals which were inoculated. Bollinger repeated the work of these two investigators on a vast scale, and confirmed their results in every particular. Tappeiner also imprisoned two rabbits in a closed cage, and allowed a tuberculous patient to cough into the cage. At the end of two months the animals were found to be free from all taint of tubercle.

The results of these researches are all the more astonishing when the fact that in every instance the atmosphere was thoroughly exposed to the sources of tubercular contamination is taken in connection with the other fact that both rabbits and guinea-pigs are intensely susceptible to the tubercular poison. Surely the atmosphere here, if anywhere, must have contained tubercle-bacilli, and if not in number sufficient to produce infection, even when inoculated, how can infection possibly occur under ordinary atmospheric conditions?

Unequal Distribution.—The non-contagious nature of pulmonary tuberculosis is also strikingly manifested when it is compared in point of distribution with well-known contagious diseases. The invasion of a disease like smallpox, for example, implies an epidemic, and a rapid exhaustion of the soil on which it thrives, after which it quickly declines. Its death-rate, no matter how large or how small, is never constant, but rises to a maximum one year and falls to a minimum the next, and then nearly or entirely disappears for a number of years, only to reappear and to re-exhaust the soil which has matured during its absence. But pulmonary tuberculosis never becomes epidemic, and has no soil to exhaust through contagion, unless it is the soil of human life. Its death-rate is so uniform from year to year that it becomes dolefully monotonous. During the last four years of which we have a record the number of deaths in the city of Philadelphia were nearly the same for each year, being 2809 in 1882, 2798 in 1883, 2801 in 1884, and 2821 in 1885; while, on the other hand, there were 1336 deaths from smallpox in 1881, and only 3 in 1885. It is thus seen that the course of a contagious disease is erratic, and that of pulmonary tuberculosis is so constant that a knowledge of its past enables us to foretell its mortality in the near future.

Then, again, if pulmonary tuberculosis is contagious, why are we able to predict with a great degree of certainty that the badly-nourished; those who are overworked, confined in-doors with sedentary employment; those who are overcrowded, or exposed to dampness; those who belong to a heterogeneous population; those who spend long terms in prisons; those who have weak circulatory organs; or those who are the youngest members of numerous families, are, if other things are equal, most prone to die of it? Has ever a contagious disease been more fastidious in the selection of its victims?

Or, again, can contagion account for the fact, which Dr. Schnyder has so well shown in the article already quoted, that while in proportion to the male sex there are more females in German cities than in the country, yet 7.21 per cent. more females suffer from the disease in the country than in the city? Will any one be bold enough to pervert reason and say that the purer air of the country contains more bacilli or contagium germs than the city air? or will he, with Dr. Schnyder, believe that the greater liability of the females in the country is due to the fact that they are greatly more exposed to overwork and to all kinds of weather and temperature than their city sisters?

Quarantine.—If any further evidence were needed to prove that pulmonary tuberculosis is not spread by contagion, it could be found in the fact that the most rigorous quarantining and isolation of tuberculous patients has not the slightest influence in modifying the fatality of the disease, as is attested by the following history: In the year 1782* the authorities of the city of Naples decided that pulmonary tuberculosis was contagious, and logically enforced the most stringent preventive laws imaginable. Every practitioner of medicine was compelled to report every case of pulmonary phthisis immediately after discovery. Neglect of this duty exposed him to a fine of three hundred ducats, and the second offence was followed by imprisonment. Indigent patients were placed in a hospital at once. Their clothing and all their belongings were carefully isolated, and an accurate record kept of them. The punishment for non-compliance with this law was imprisonment. All furniture exposed to infection was ordered to be burned. After the patient's death or restoration his room was thoroughly renovated,—

* Uffermann, *Berlin. Klin. Wochenschrift*, 1883, No. 24; cited after Brehmer.

the floor, doors, and windows were taken out and burned, and new ones substituted. A heavy fine was imposed on those who bought or sold clothing which was exposed.

This law was in full force up to the year 1848,—for a period of sixty-six years,—and yet during that time there appears no evidence to show its practical usefulness; but, on the other hand, Dr. Rienzi says “that the injury which it inflicted on the city of Naples is simply indescribable.” Patients and their friends became objects of execration; houses in which a death occurred from the disease depreciated in value, and their owners became impoverished. A similar law existed in Portugal for many years, and was followed by like disastrous results.

In summing up the evidence which has been adduced in these pages, it appears from the first portion that nearly all the organic diseases of the human body are infectious, but that some, on account of the facility with which their germs multiply and diffuse through the atmosphere, are very readily communicated, while others, which possess these properties in a small degree only, are not readily communicated. The former we have called the contagious, and the latter the non-contagious diseases. Continuing this line of reasoning, we saw that pulmonary tuberculosis clearly belongs to the second or non-contagious class of diseases. In the second or clinical portion we found corroborative evidence of the first portion. Here the danger of exposure; the intimacy between husband and wife; the tubercle-bacilli, or the tubercular virus in the atmosphere; the distribution of the disease; the effects of quarantine; were all discussed in the light of contagion, and nothing was discovered to show the slightest danger of communicating this disease from one person to another under ordinary conditions.

In conclusion, we trust that altogether we have offered sufficient proof for believing that pulmonary tuberculosis is entirely due to influences other than those which are swayed by evil genii residing in the air; and hope that we have succeeded in allaying the morbid fear and the abomination with which consumptive people have recently come to be regarded by the medical profession, by their friends, and by all with whom they come in contact.

CUNEIFORM OSTEOTOMY FOR ANTERIOR CURVATURE OF BOTH TIBIÆ AND BOTH FIBULÆ:

ILLUSTRATING THE GREAT PRACTICAL VALUE OF THE ELECTRO-OSTEOTOME AS A BONE-CUTTING INSTRUMENT, AND THE SPHENOMETER AS AN INSTRUMENT OF PRECISION IN BONE SURGERY—SUTURING OF THE BONES WITH KANGAROO TENDONS—HYDRONAPHTHOLIZED SURGICAL DRESSINGS—BRUCE'S BOW-LEG BRACE.*

BY MILTON JOSIAH ROBERTS, M.D.†

GENTLEMEN:—The patient whom I present to you to-day is a colored boy 4 years of age. He has been brought to this clinic from Newburgh-on-the-Hudson, a distance of some sixty miles. He is the youngest of a family of seven children, five of whom are living. He has a rachitic history. He was two and a half years old before he began to walk, and he has such an aggravated deformity that he has never been able to walk with any degree of comfort.

As I have not previously had an opportunity of getting a photograph of this patient, I have brought with me my camera, together with some dry plates, that I may make a pictorial record of his deformity. (The patient was at once placed in a sitting posture on a small table covered with a white sheet. The nurse stood at the farther side of the table, and held up a white sheet, which served as a background. Prof. Roberts quickly placed his camera in position, focused the image of the patient on the ground glass, put a plate-holder in position, and exposed one of the sensitized plates, occupying in all not more than a minute and a half of time. The negative was subsequently developed, and Fig. 1 was made from it.—REPORTER.)

I think it is of the greatest possible importance, in making records of examples of deformity, to have photographs which illustrate them. They give the best idea of the deformity in the shortest space of time, and as evidence of the existence and extent of a deformity will usually rank higher than almost any other form of record.

Now for the geometrical observations which

FIG. 1.

Negro, showing deformity.

should always be made in cases of this kind.* While a photograph representing the deformity is of great service in giving a general idea of the extent of aberration, it does not furnish us with all the desired information, and, even if it did, the expense of reproducing photographs in the form of cuts is so great that it cannot always be borne by those who have cases to report. It is desirable, therefore, to have an additional record of the degree of deformity, which record shall be in terms that are intelligible to those who may seek information from its perusal. To this end it is necessary to employ an instrument of precision. The instrument which, in my judgment, is best adapted to determine the extent of aberration in degrees, in examples of deformity of this kind, is a protractor, which I have had constructed for this special purpose. This protractor (Fig. 2) is furnished with two sets of graduations, and three series of figures marked on the face of the semicircle. Both arms of the instrument are made adjustable. One of these arms slides in a groove, which passes through the base of the graduated semi-

circle. In using the instrument this arm is placed so as to correspond to what should be the normal plane of that part of the body which is the subject of observation. The other arm is secured in a revolving head-piece, so that one of its edges corresponds to or passes through the centre of the base of the graduated semicircle. This arm can be rotated so as to correspond with the plane of the deformity, and the number of degrees of aberration is then read off from the graduated circle. Proceeding to measure the deformity in this case, in the manner I have described, we find the extent of the anterior curvature of the bones of the right leg is forty-five degrees, and of the left leg forty-three degrees. A little farther on you will see that these observations not only serve as a useful record of the extent of deformity, but will be indispensable to the employment of another mathematical instrument to be used in determining the dimensions of the base of the wedges to be removed to correct the anterior deformity of the tibiae and fibulae.

The bone-cutting instrument which I will use in performing the operation for the correction of this deformity is one that has been devised and elaborated by myself, and which I have called the electro-osteotome.† (See

* "Anatomical Geometry and Toponymy. An Introduction to the Scientific Study of Deformities, with a Description of New Mathematical Instruments." Read before the Medical Society of the State of New York, February 3, 1885; *The Medical Record*, February 21, 1885.

† "Description and Practical Demonstration of the Working of Roberts's Improved Electro-Osteotome, New

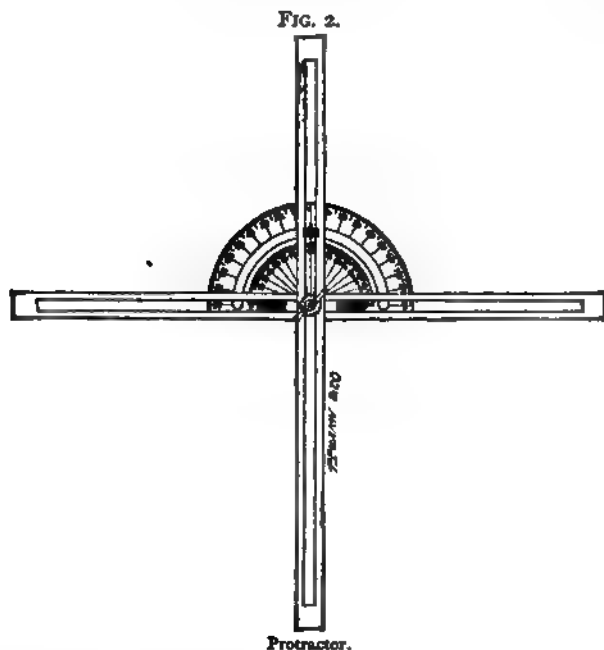

Fig. 3.) It has been designed with special reference to the rapid and accurate cutting

of bone. When I began some years ago to perform operations in bone surgery, I found

Electrical Illuminating Apparatus, and a New Form of Portable Storage-Battery." Communicated to the New York Academy of Medicine, February 19, 1885; published in the *New York Medical Monthly* for October, 1886.

that we were not as well provided with means for cutting bone as we should be. In order to operate satisfactorily upon bones, it seemed to me that we should be able to cut them with as much ease and accuracy as we cut the soft parts with a sharp scalpel. The chisel, which, for the most part, has been the bone-cutting instrument heretofore employed by surgeons in their conservative operations, does not fulfil these indications. In the electro-osteotome, however, as will

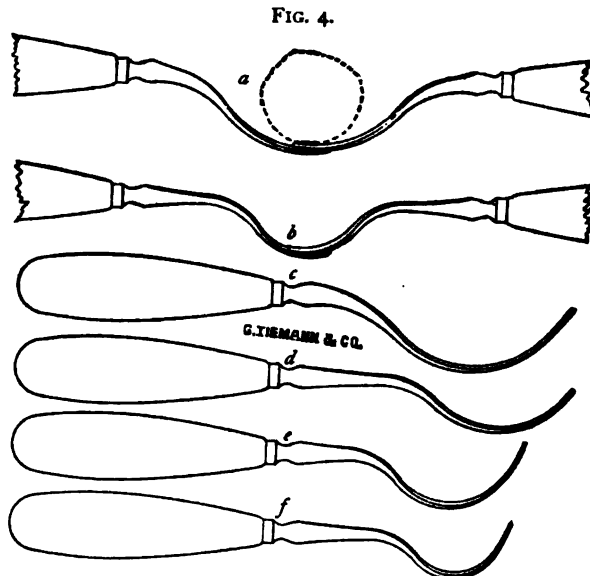

places the surgeon in full command of the situation, and enables him to promptly meet all indications. I have now performed a large number of operations with the electro-osteotome, and am thoroughly convinced that it is far superior to any other instrument in existence for performing the varied opera-

tions in bone surgery. The instrument which I will use on the present occasion is a new one, and has some improvements over the old one which I have been using for a number of months. As this is the first time I have had occasion to use it since it came from the shop, I hope you will make allowance for any delay that may arise in consequence.

The patient having now been anæsthetized, and his lower extremities thoroughly cleansed, first by the use of soap and water, and subsequently by rinsing in a solution of corrosive sublimate (1 to 1000), a carbolized Esmarch's bandage is tightly applied, beginning at the toes and carrying it up the limb to the upper part of the thigh, where it is made fast. Re-

at *a* and *b* are in pairs, while those at *c*, *d*, *e*, and *f* are single, and are provided with much longer blades, which are curved up so as to serve the same purpose as a pair of retractors with shorter curves. The single retractors are much more difficult of introduction on account of the increased length of curvature. These retractors are placed in position by passing them in around the bone, between it and the soft parts, so that when they are in position the bone lies directly upon them and the soft parts are behind them. In this way the soft parts are absolutely protected from all danger of being cut while using the circular saw of the electro-osteotome.

The bone being thus exposed, its exact diameter at the site of operation is readily de-

Form of protecting retractors.

moving the lower part of the bandage, we have a bloodless limb upon which to operate.

The first step in the operation is to make a longitudinal incision down to the bone along the anterior aspect of the tibia over the site of the greatest deformity. Care should be taken in making this incision not to carry the knife through the periosteum, thus injuring it unnecessarily. Having made a clean-cut incision down to the bone, the soft parts on either side of the incision are picked up with a pair of dressing forceps, and the cellular tissue between them and the bone is divided with a scalpel, so as to admit, without the use of undue force, the end of the protecting retractor which is placed between the soft parts and the bone.

The forms of protecting retractors used for this purpose are illustrated in Fig. 4. Those

terminated by means of a pair of calipers. The diameter of the right tibia we ascertain to be in the present instance twenty-four millimetres.

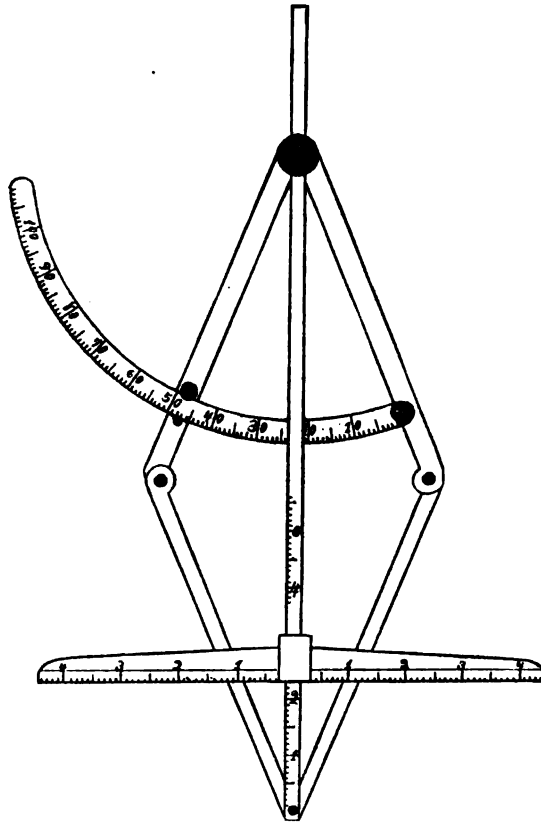

The next step is to determine the exact dimensions of the base of the wedge of bone to be removed in order to correct this deformity. For this special purpose I have invented a mathematical instrument* (Fig. 5), which, given the degree of deformity to be corrected and the diameter of the deformed bone, will automatically calculate the dimensions in millimetres of the base of the wedge of bone to be removed to exactly correct the deformity, thus saving a somewhat elaborate trigonometrical calculation. This instrument—the

* "The Sphenometer; a New Instrument of Precision in Bone Surgery;" *New York Medical Journal*, November 20, 1886.

sphenometer—is used as follows: The lateral shafts, all four of which are of the same length, are set so as to enclose the angle of deformity. We have already determined in the present case that the angle of deformity is forty-five degrees, therefore we move the instrument so that the inner edge of the lateral shaft over which the graduated arc passes coincides with the line indicating forty-five degrees on the arc. (See Fig. 5.) Thus set, the lateral arms of the instrument enclose an angle equal to the degree of deformity. It

diameters of bone and corresponding increasing dimensions of base of wedge.) We have determined the diameter of the right tibia in the present instance to be twenty-four millimetres. Upon the central arm of the sphenometer, which is graduated in millimetres, a straight bar, also graduated in millimetres from its middle towards either end, is made to slide at right angles to it. This graduated bar, at right angles to the central shaft, is moved along until the diameter of the bone at the site of operation has been

FIG. 5.

Sphenometer.

will be understood, from an examination of the diagram (Fig. 6) that the sides of the wedge-shaped piece of bone to be removed to correct this deformity, indicated by dotted lines *c*, *x*, *d*, must be inclined to each other, so as to enclose an angle of equal extent to that of the deformity, *d*, *a*, *b*, to be corrected, viz., forty-five degrees. Having set the instrument so that its lateral shafts enclose the angle of aberration, it can readily be seen that the dimensions of the base of the wedge depend entirely upon the diameter of the bone at the site of the operation. (See Fig. 6, in which *j*, *k*, *h*, *i*, and *f*, *g* represent varying

measured off on the central arm of the sphenometer. (See Fig. 5.) Having done this, we can now read off from the graduated bar, which passes over the lateral limbs of the instrument, the dimensions in millimetres of the base of the wedge of bone necessary to be removed in order to correct the deformity. It will be seen by reference to Fig. 5 that the straight movable bar is graduated both ways from its middle, and therefore it is necessary, when reading off the dimensions of the base of the wedge, to count the graduations included between the lateral shafts of the instrument on both sides of the central shaft. The base of

the wedge we find in the present instance to be eighteen millimetres. (See Fig. 5, nine millimetres being indicated on either side of the central shaft of the sphenometer.) Eighteen millimetres are, therefore, marked off on the convex surface of the bone. Selecting an imaginary point on the opposite side of the bone, midway between the millimetre markings on the convex side, I take the electro-osteotome in hand, close the circuit, and cut obliquely through the bone to the imaginary point on the opposite side, such division of

we will proceed to do for the fibula what has already been done for the tibia. Instead of endeavoring to get at the fibula through the opening which I have already made, I will make a separate opening upon the external aspect of the limb through which to reach the fibula and cut down to it. Placing the protecting retractors in position, the bone is brought into full view, as already described. By the use of the bone calipers I can now readily measure the diameter of the bone. This I find to be ten millimetres. With the

FIG. 6.

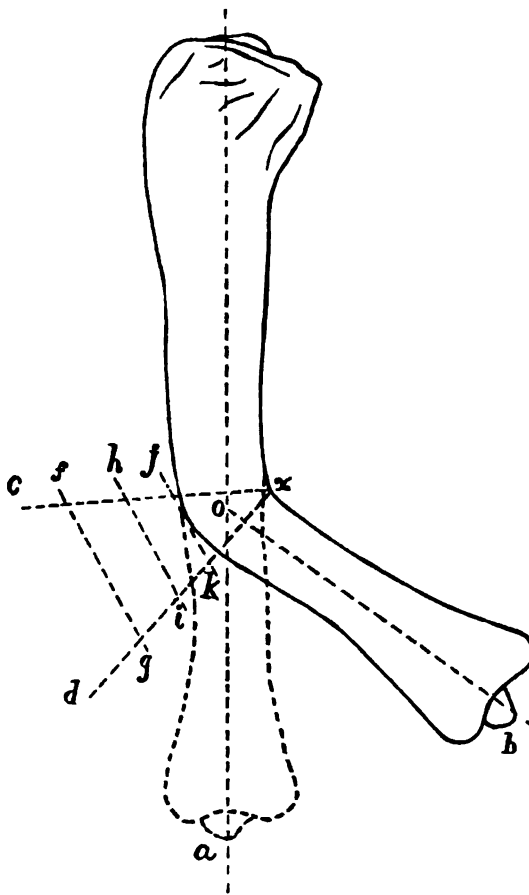

Diagram of tibia, showing wedge to be removed.

the bone requiring, as you observe, only about two seconds. The second oblique section of the bone is begun eighteen millimetres away from the first on the convex side of the bone, and the direction of the cut is such as to reach the opposite side of the bone at the same point as in the first section. Removing this wedge and coaptating the two cut ends of bone, it will be found that the deformity has been completely and perfectly reduced. But the cut ends of this divided tibia cannot be coaptated until we have removed a small wedge of bone from the fibula. Therefore

sphenometer set at the angle of aberration, viz., forty-five degrees, I move the graduated bar, passing over the lateral shafts of the sphenometer along until ten millimetres have been measured off. I can now see at a glance that the base of the wedge to be removed from the fibula measures nine millimetres. I proceed, therefore, to cut out this wedge by means of the electro-osteotome in the same manner that I did for the tibia.

These wedges of bone having been now removed from the tibia and fibula, and the distal end of the limb so placed as to coaptate

the cut ends of bone, you see that the anterior deformity has been completely and accurately corrected. There has been no undue force used, no jarring, pulling, tearing, or laceration of tissue, such as is incident to the use of the chisel and mallet. No undue manipulation or force is required to bring the limb into line when the proper-sized wedges of bone have been removed. If any of you, gentlemen, have ever been present at an operation for the correction of a deformity of this kind, where the chisel has been used as the bone-cutting instrument, you cannot have failed to have noticed the great muscular exertion sometimes necessary on the part of the surgeon to get the limb into line after he has ceased to use the chisel. The reason of this is that the bone is, as a rule, only partially divided by the chisel. The remaining portion is then broken off by manual force, and the limb carried, if possible, slightly beyond the point necessary to correct the deformity, and

move the Esmarch's bandage as before. We are now ready to again direct our attention to the right limb. Sufficient time has elapsed since the removal of the Esmarch's bandage from the right thigh to permit the blood-vessels and capillaries to regain their former tonicity, so that no annoyance from oozing of blood need be apprehended. I shall, therefore, remove the bandage which has secured the sponges in place, and proceed to pass a suture through the divided ends of the bones, so as to hold them in perfect coaptation during the healing process. To this end I replace the circular-saw head-piece of the osteotome with that designed for the carrying of drills. Introducing a fine drill, I make the necessary drill-holes in the bones, one at each end, for the purpose of passing the sutures through. Instead of drilling through the bone at right angles to its long axis, I am in the habit of commencing about half an inch from the margin of the cut on the convex aspect of

FIG. 7.

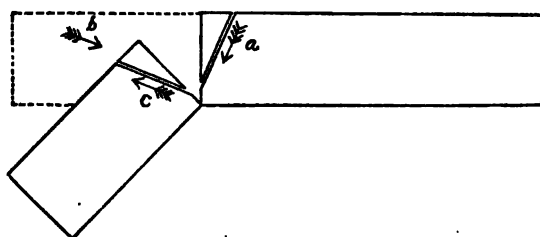

Diagram showing position of drill-holes and direction of passing sutures through the bones.

the dressing applied. No such clean-cut or complete section of the bone as the electro-osteotome makes is made, and no instrument of precision serves to guide the surgeon in his manoeuvres. It is my belief that by such or similar means as you have seen me use to-day, bone surgery, so far as the correction of angular deformity is concerned, is capable of being practised as an exact science, thus doing away at once with all guess-work. Placing antiseptic sponges over the site of these incisions, and securing them in place by a firmly-applied roller-bandage, the Esmarch's bandage is removed from the upper part of the thigh, and the blood again permitted to flow through the limb.

Leaving the right limb for the present thus bandaged, we will proceed to operate in precisely the same manner upon the bones of the left leg. Having completed the removal of the wedges of bone from the tibia and fibula of the left limb, we place carbolyzed sponges over the sites of the incisions, secure them in place by means of a roller-bandage, and re-

move the bone, and inclining the drill at such an angle as will permit it to emerge on the cut end of the bone, nearly on the opposite side, as indicated by the arrow *a*, Fig. 7.

To retain the cut ends of the bone in coaptation, I am in the habit of using absorbable sutures instead of wire. After the dressing is applied, which, of course, is a permanent one, the sutures are absorbed, and the union of bone goes on uninterruptedly. Of late I have been making use of tendons from the tail of the Australian kangaroo, kindly forwarded to me for trial by Mr. A. E. Beach, of the *Scientific American*, who received them direct from Australia. These tendons are exceedingly strong, and are not as readily absorbed as the ordinary catgut sutures, remaining intact for a period of from eight to ten or more days without artificial preparation. I have forwarded some of them to Mr. Geo. J. Seabury, manufacturer of surgical dressings, and he informs me that in strength they are superior to any substance he has ever seen used for absorbable sutures.

I have also written to Australia for a fresh supply, and hope ere long that these tendons, properly prepared and assorted, will be placed upon the market, as I believe them to be of great practical service where a strong absorbable suture is required. In the introduction of these sutures I make use of an instrument of the form illustrated in Fig. 8. To intro-

are held in complete apposition. This we have already done by means of sutures of kangaroo tendons. It is intended that the dressings which are applied shall not be removed until four to six weeks have elapsed. Unless I can make arrangements so that the patient can be retained here in the hospital, the mother will, with my permission, take this

FIG. 8.

Instrument introducing sutures.

duce the suture, it is laid in the fork at the end of the instrument, and shoved down through the drill-hole, as indicated by the arrow *a*, Fig. 7, and out into the space left by the removal of the wedge-shaped piece of bone. Withdrawing the instrument, the suture is left in position. By means of the side hook near the end of the instrument the suture is picked up and drawn through as far as desired, when it is again released. The instrument is now passed down through the drill-hole in the other cut end of the bone, as indicated by the arrow *b*. It is pushed out through the lower opening, and the suture engaged by means of the hook. The instrument is then withdrawn, as indicated by the arrow *c*, and with it the suture. The cut ends of the bone are now placed in apposition, as indicated by the dotted lines, Fig. 7, and secured by tying the suture.

Having now secured the divided ends of the tibia and fibula in apposition by kangaroo tendons, the incisions through the soft parts are closed by means of a continuous suture of the same material. For a long time I was in the habit of applying the permanent dressings in operations like this without suturing the bones, and have had most excellent results from this practice. I have never had a single example of non-union, and in only one instance was there delayed union. Extraordinary care, however, is necessary in applying the permanent dressings, without suturing the bones, to keep their cut ends in apposition. By using absorbable material instead of wire to hold the ends of bones together sutures cease to be objectionable, while at the same time absolute certainty of apposition of bone is secured.

Now as to the dressing of these cases. This is a matter of considerable importance; in fact, a chief feature in the successful issue of such operations. The first essential condition is to be certain that the cut ends of bone

child to Newburgh this evening. So you see we have some confidence in the method adopted in the treatment of these cases.

Plaster of Paris, silicate of sodium, and other substances may, in conjunction with strips of cloth, be used in making retentive splints for cases of this class. Wire gauze may also be used. Gutta-percha is the material, however, which I prefer above all others for this purpose. When made pliable by being dipped in hot water it can be perfectly moulded to any part of the body, and when set never becomes soft by discharges from wounds or other sources. It has the advantage over plaster of Paris in being a cleanly dressing to apply, not soiling the hands or clothes. It is made in sheets of varying thicknesses. One of a quarter of an inch in thickness will be used on the present occasion. Holes should be punched in the sheets before they are cut up for use, so as to permit of the evaporation of the insensible perspiration from that part of the body to which it is applied. This may be done by ruling the surface of the sheet both ways, with lines about two inches apart, which cross each other at right angles, and punching holes with a punch at the intersection of these lines. Thus prepared, the gutta-percha is dipped into boiling water, or water heated to very nearly the boiling-point, and when thoroughly softened it is applied to the limb, which is held in position until the gutta-percha sets. As the gutta-percha begins to set very soon after it is removed from the hot water, it is of course essential to apply it as quickly as possible. It is of great advantage also to have the help of an assistant who is thoroughly familiar with the manipulation of gutta-percha and the various steps of the operation. It should be secured in position by means of a roller-bandage carried about it and the limbs. While still soft, any parts of the splint which project unduly may be readily trimmed off with a pair of scissors.

But, before the gutta-percha splint is applied, it is desirable to put some form of antiseptic dressing about the limb at the site of operation. In the past I have made use of carbolic acid, iodoform, and corrosive sublimate gauze. More recently I have been using hydronaphthol, which is a new antiseptic, and was introduced to the profession, I believe, by Dr. George R. Fowler.* I have been using it now for some time, and am very well pleased with it indeed. In fact, I may say I am quite of the opinion that it has a

form and corrosive sublimate dressings are frequently reported in our medical journals. If, therefore, we have in hydronaphthol, as it appears, thus far, from all reliable sources of information, a non-poisonous and non-irritant antiseptic, it will meet with a hearty welcome from a large number of surgeons. It is used in the same strength solutions as corrosive sublimate.

Along the line of incision hydronaphthol in the form of powder is sprinkled. It may be mixed with equal parts of fuller's earth, if

FIG. 9.

Patient with limb dressed.

very brilliant future. The advantages claimed for hydronaphthol are its efficiency as an antiseptic and an antiputrefactive agent. It belongs to the phenol series. Though irritating to mucous membranes, it is a non-irritant to wounds. It is non-poisonous and non-corrosive, and on this account is far safer than carbolic acid used in strong solutions. It has been demonstrated that carbolic acid, in weak solutions at least, is a very unreliable antiseptic. Cases of poisoning from the use of iodo-

thought desirable, and used upon closed wounds in the same manner as iodoform. Over this a pad of six or eight thicknesses of hydronaphthol gauze is placed, and secured in position with a roller-bandage of hydronaphthol gauze carried about the limb.

Thus prepared, the limb is ready to be placed in the retentive splint of gutta-percha. When the gutta-percha splints have been applied in the manner already described, and secured in position by roller-bandage, our patient is ready for transportation. (See Fig. 9.) Usually patients thus operated upon and thus dressed will recover without an un-

* *Vide The New York Medical Journal*, October 3, 10, 24, and December 5, 1885.

toward symptom. They should, however, be carefully watched, the temperature being taken twice or three times daily. If there is a rise in temperature above 101° , which cannot be traced to any outside source of irritation, the wound should be examined at once. In very young children the greatest possible care is essential in keeping the dressings perfectly dry. The patient should be placed in bed, and the legs inclined at an angle of about forty-five degrees from the surface upon which he is lying. Kept in this position, the dressings are not likely to become soiled by urine or other excreta.

(To be continued.)

ANTIFEBRIN.

BY WILLIAM OSLER, M.D.*

A FEW months ago Drs. Cahn and Hepp announced from Kussmaul's clinic the discovery of a new antipyretic, which they named antifebrin. A full account of their observations has more recently appeared in the *Berliner Klinische Wochenschrift*, Nos. 1 and 2, 1887.

The drug is known chemically as phenylacetamide or acetanilide ($C_6H_5C_6H_4OHN$), and is formed by the action of heat upon aniline acetate. It is a neutral body, and in this respect it differs from all other antipyretics, which are either phenols, like salicylic acid and resorcin, or bases of the chinoline series, as thallin, antipyrin, and quinine. It is a white crystalline powder, insoluble in cold water, but readily dissolving in hot water or alcoholic solutions. The taste is not unpleasant. The dose is from 8 to 12 grains. In larger amounts it is not poisonous, though it is advisable not to exceed 30 grains in the day. Usually 8 grains will be found an effective dose. It is conveniently given in spirit and water, or in whiskey, or, for children, in warm sweetened water.

During the past three months I have used it in my wards at the Philadelphia Hospital and at the Hospital of the University of Pennsylvania in the following 29 cases: typhoid fever, 7; pneumonia, 6; phthisis, 8; erysipelas, 4; pleurisy, 1; peritonitis, 1; rheumatism, 1; intermittent fever, 1. As a rule, 8 grains were given when the temperature rose above $103\frac{1}{2}^{\circ}$, and hourly observa-

tions were made for six or eight hours. In several cases of phthisis 4 grains were given four or five times a day. The maximum amount given in one day was 32 grains (Case II.). For brevity, the effects of the drug may be noted under the following heads:

1. *Reduction of Temperature.*—This is the most marked and characteristic action, beginning usually within an hour. In eighteen administrations the fall was over 2° in this time; in three instances a fall of 3° , on two occasions a fall of 4° . In thirteen instances the temperature was reduced 4° in two hours, in sixteen administrations 3° , and on four occasions 5° . The greatest drop within this time was in Case XXIV., in which the fall was $6\frac{1}{2}^{\circ}$. The greatest reduction was in the following: Case I., 8° in five hours; Case X., $6\frac{1}{2}^{\circ}$ in five and a half hours; Case XVIII., $7\frac{1}{2}^{\circ}$ in two and a half hours; Case XX., 7° in seven hours; Case XIX., $7\frac{1}{2}^{\circ}$ in ten hours.

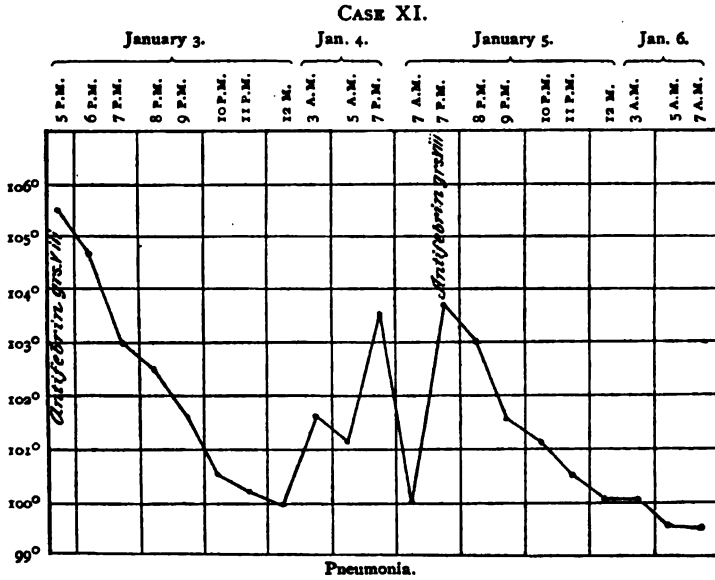

In seven administrations the temperature was unaffected by the eight grains. Cases VII. and XIII., both of pneumonia; Case XXIII., peritonitis; and Cases IX. and XVIII., erysipelas.

The duration of the reduction was variable, usually from three to six hours. The following cases illustrate well the antipyretic action of this drug:

CASE XI. (Chart I.).—Man, aged 32, admitted to the drunkards' ward of the Philadelphia Hospital. A few days after admission he was noticed to be a little short of breath, and, on examination of the lungs, there was dulness, with râles and feeble blowing breathing at the right base. On January 3, at 5 P.M., the temperature was $105\frac{1}{2}^{\circ}$. Antifebrin, gr. viii, was given, and the fever gradually fell, as the chart shows, until midnight, reaching 100° . By 3 A.M. it had risen to $101\frac{1}{2}^{\circ}$. At 7 P.M. on the 5th the temperature was nearly 104° , and another dose of the antifebrin was given with good effect.

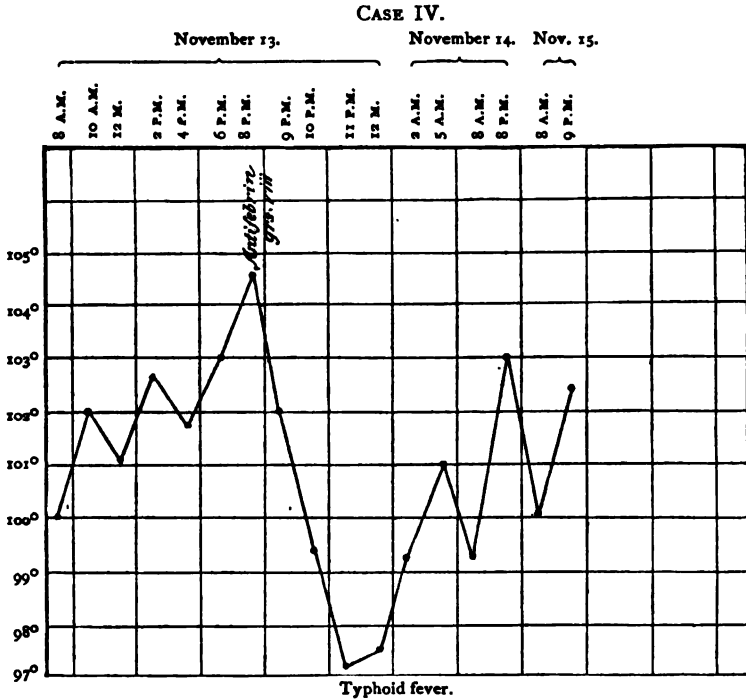

CASE IV. (Chart II.).—Rachel C., aged 21, admitted November 3 with typhoid fever. On the 4th the temperature was 104° , but from this date until the 13th it did not rise above 103° . At 8 P.M. on the 13th the temperature was $104\frac{1}{2}^{\circ}$. Antifebrin, gr. viii, was given. By ten o'clock there was a fall of 5° , with profuse sweating. At 11 P.M. the temperature was 97° . At 12 A.M. it began to rise, and by 2 A.M. was 99.4° . Between eleven and twelve o'clock she complained of slight chilliness, but the general condition was good, and there was no collapse. The thermometer did not again register above $103\frac{1}{2}^{\circ}$ in her case.

* Professor of Clinical Medicine in the University of Pennsylvania.

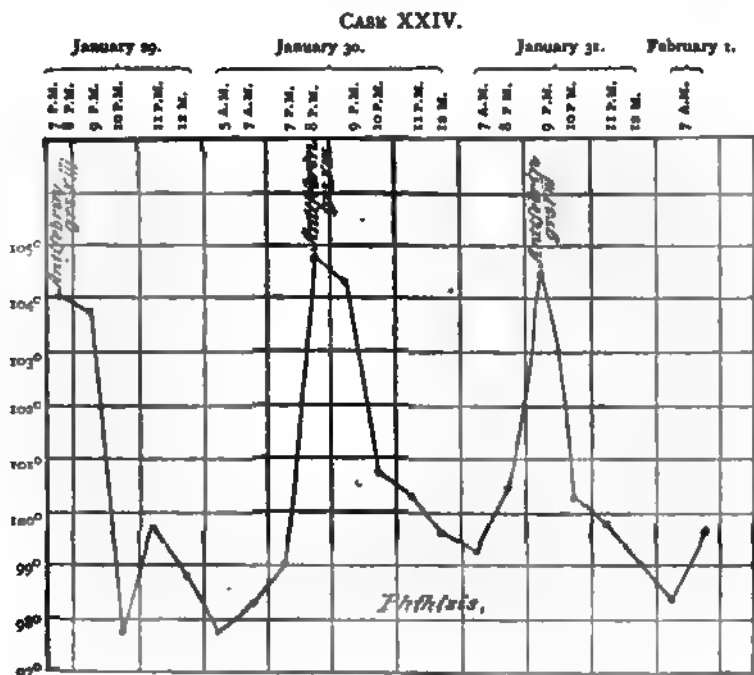

CASE X. (Chart III.).—J. B., aged 35, with chronic phthisis and high fever. The chart shows how rapidly the antifebrin in three successive days reduced the temperature from 4° to 7° in from two to three hours.

above 103°, and a second dose of antipyrin was given. At 5 P.M., quinine, gr. xx. He had had also quinine, gr. v, every four hours. At 8 P.M. the temperature had fallen to 100½°, at 11 P.M. to 99°, and at 3 A.M. to 98°. On

CASE XVIII. (Chart IV.).—F. H., aged 31, was trephined for mastoid disease in Philadelphia Hospital January 15. On the 20th he was attacked with erysipelas. On the 23d, at 10 A.M., the temperature was 106½°; at 11, 105½°. He was given antipyrin, gr. xv, and quinine, gr. xx. At 3 P.M. the temperature was still

the 24th the fever was again 105°, and antipyrin and quinine were given, with a reduction of 4° in five hours. On the 25th antipyrin and quinine were twice given, without any effect. He was transferred to the medical ward, and the antifebrin was used as shown by the chart. The last dose caused a

fall of $7\frac{1}{2}^{\circ}$ in two and a half hours. The patient subsequently did well. The chart is of interest, as it affords a comparison between the action of antipyrin with quinine, and that of antifebrin.

In several cases the dose of gr. viii did not seem sufficient. In seven administrations little or no effect followed. This was particularly noticeable in the pneumonia cases. In Case XIII., with almost complete involvement of the right lung and affection of the left base, the temperature from the 5th to the 10th ranged from 102° to 105° . Antifebrin was given six times, thrice without effect, and on three occasions it only reduced the fever a degree or a degree and a half. Thallin, gr. iv, twice brought the temperature down 3° and 4° ; but the most effective agent in this case seemed to be the cold pack, which reduced the temperature from 105° to $98\frac{1}{2}^{\circ}$. This patient had delayed resolution, and the fever did not subside until the thirty-ninth day from the initial chill. In other instances, a second dose repeated an hour or more after the first produced the full effect, as in Cases XI. and XVIII.

In typhoid fever the action was usually prompt and satisfactory. In Case II., a young man, aged 25, with persistently high temperature and marked nervous symptoms, the drug was given on fourteen occasions, and after each dose there was a drop of from 3° to 5° . In the milder cases the effect was more striking, as in Case IV.

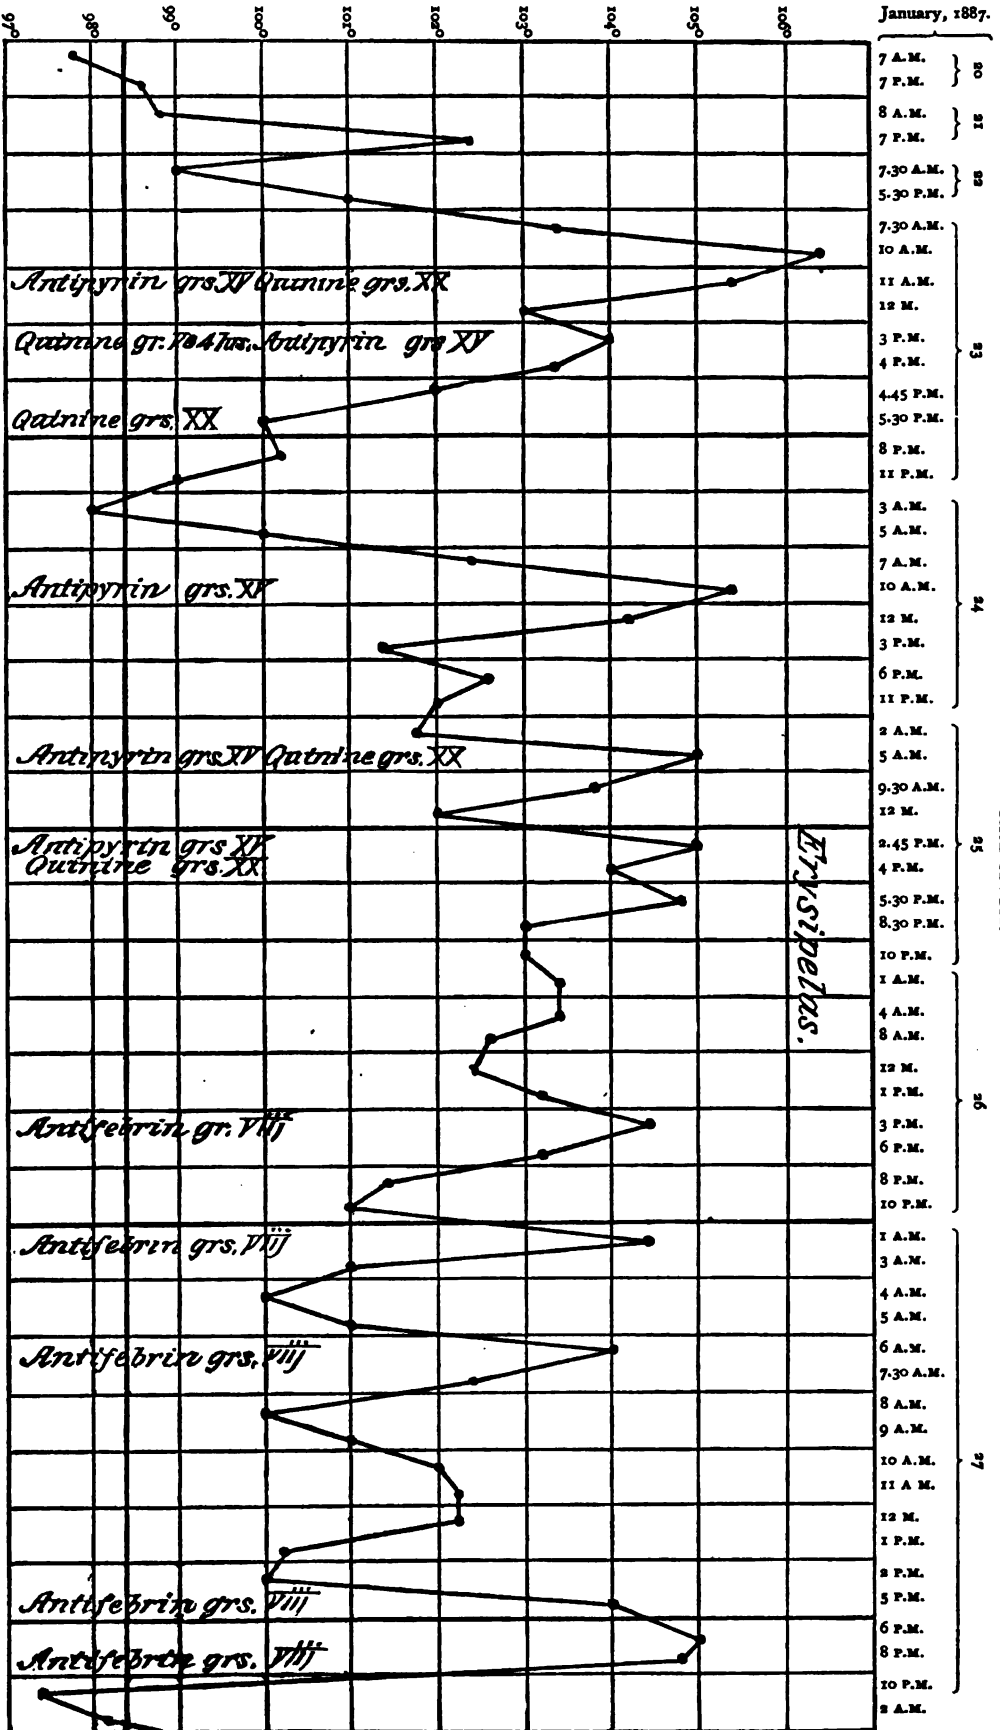

In the erysipelas cases the action was in each instance most decided.

In phthisis, with high fever, the drug was usually given in a single powder of gr. viii, when the temperature was above 103° , but in three cases the plan was tried of giving gr. iv four or five times a day. This did not seem very successful, and the patients did not feel so comfortable as with the single dose.

In a remarkable case of quartan ague antifebrin in 8-grain doses given before or during the paroxysm seemed to be without effect. One curious circumstance, however, is worth mentioning. The lad had always with the fever the most intense general urticaria, which the antifebrin seemed to prevent, much to the patient's comfort.

2. *Action on the Circulatory System.*—Usually with the reduction of the fever the pulse would fall, and a drop of 20 or 30 beats in two or three hours was frequently noted. Thus, in Case II., with a pulse-rate of 112 per minute, and the temperature at 105° , the pulse fell to 84 in four hours. In another case the pulse fell from 130 to 90 in four hours. A marked increase in the pulse-tension was observed in several cases. Even with a rapid fall of from 5° to 7° in two or three hours, there was no evidence of heart-weakness. Slight cyanosis, which is mentioned by one or two German writers, did not occur in any instance.

3. *Sweating.*—As with thallin and antipyrin, the action of antifebrin is almost invariably

CASE XVIII.

accompanied with profuse perspiration, which is often the first effect of the drug. Repeatedly I have seen the forehead beaded with sweat half an hour after the administration of 8 grains. This is sometimes a most unpleasant feature in the employment of the drug, and is the only one of which the patients have complained. In several instances the drug was combined with atropine, but without much effect. It does not seem to increase the night-sweats in cases of phthisis; indeed, under its use, one patient, who sweated much with the afternoon dose, had drier and, in consequence, more comfortable nights. In the severe typhoid case already referred to, I stopped its use, as the sweating seemed to weaken the patient.

4. *On the Urine.*—The only change noted was a marked increase in the amount in some of the cases. This is probably a direct result of the increased arterial tension.

5. The effect on the general condition seemed usually beneficial. A quiet sleep often followed an hour or so after its administration. The phthisical patients expressed themselves more positively than the others in this matter.

There were none of the disagreeable effects which we sometimes see follow the use of antipyrin and thallin. There was no instance of vomiting; and, with the exception of Case IV., there was no shivering or chilliness, such as is so common after antipyrin.

These limited observations confirm those of Cahn and Hepp and others, and I think that we have in antifebrin a prompt and powerful antifebrile agent, easy to take, and free from unpleasant effects. It has the advantage also of cheapness. Merck's article, which I have used, is only sixty cents an ounce, wholesale.

PHARMACOLOGICAL CONTRIBUTIONS FROM
THE UNIVERSITY OF PENNSYLVANIA.

THE PHYSIOLOGICAL ACTION OF THE
VALERIANATE OF AMMONIUM ON
THE NERVOUS SYSTEM.

BY WM. E. PARKE, M.D., PARKESBURG, PA.

SO far as I have been able to learn, no study has been made of the physiological action of valerianate of ammonium on the nervous system, and whatever value may attach to the conclusions arrived at in this paper, the experiments will at least have the merit of being the first in the field.

A number of experiments were first made on the frog to ascertain the general action of the drug on the system. Large and small amounts of the solution of the drug were injected into the peritoneal cavity of the animals, and their movements noted.

Administration of small amounts was followed in a few moments by clonic contractions of muscles over the whole body, and slight exaltation of the reflex action. If the size of the dose was increased the clonic contractions gave place to tetanic spasm and reflex action was lost, and when large toxic doses were given paralysis resulted almost at once. Whether convulsions or paralysis result appears to be determined by the size of the dose. The frog passes from convulsions into stupor, and from stupor to death.

Curiously enough, the physiological action of the drug was manifested sooner and much more powerfully in the fore than in the hind extremities. Thus, after the drug was given, clonic contractions appeared first in the fore legs, and were followed by tetanic convulsions in these parts, in which the legs were drawn up firmly against the belly. At this moment the hind legs were either not affected or were in the stage of clonic convulsions. At the autopsy it was found that the animal's heart was beating after it was completely dead to all nerve-excitation, thus pointing to the fact that the drug is pre-eminently a *nerve-poison*. (See Experiments 1, 2, 3, 4, 5.)

To determine whether the convulsions were cerebral or spinal in origin, section was made through the medulla, thus dividing the brain from the cord, and the drug given. It was found that the convulsions were still present, thus showing that they must be spinal. (See Experiment 6.)

The study of the reflexes was somewhat confusing, the evidence of different experiments seeming contradictory. In working out this part of the investigation the medulla of the frog was destroyed. A few minutes were then allowed to elapse for the animal to recover from the shock of the operation. A slightly acidulated solution was prepared, and the frog was suspended, with hind extremities in the solution. The time, from the moment of immersion until a reflex action was produced, was noted at intervals of five minutes. The acid solution was carefully washed off of the frog's legs after each immersion. The acid solution would of course furnish a uniform method of irritation. After the time of reflex was ascertained, the drug was given, and a second series of observations similar to

the first was made. In some of the experiments injection of the drug was followed by an exalted reflex,—*i.e.*, the reflex appeared sooner after the drug was given than before. In others the reflexes were probably either not altered or lowered. (Compare Experiments 6, 8, 11 and 7, 10, 12.)

It appears that when a small dose of the drug is given, or when only a small amount has been absorbed, the reflexes are exalted, but when the dose is large then the reflexes are lowered. These results would seem to indicate that the drug in small doses acts as a stimulant, and in large doses as a depressant, to the spinal cord.

In cases where the cerebrum was destroyed, it was found that the animal was little affected by doses which soon took life when the medulla alone was destroyed (or probably even when all the nervous system was intact). Thus, in Experiments 11 and 12, such doses as in Experiments 7 and 9 killed, were followed by no symptoms. This would seem to indicate that the drug is more of a poison to the brain than to the cord.

In order to ascertain whether the action of the drug on reflexes was peripheral or spinal, the vessels of one hind leg were ligated, the medulla having previously been destroyed. The method of doing this was as follows: The sciatic nerve was exposed, and carefully raised so as to pass a ligature under. This ligature was passed around all the other tissues of the limb, thus cutting off the circulation to the part. Now the drug was given, and it was found that the reflex continued in both the ligated and the unligated limb. (See Experiment 13.) Of course, after the ligation, the drug could not reach the peripheral nerve-endings, and, as the reflex action was maintained, we must believe that the action of the drug is spinal.

In studying the local action of the drug, the various parts of the nervous apparatus—*i.e.*, brain, cord, and nerves—were laid bare, and a crystal of the valerianate was placed directly upon them. Previous to this, however, the normal excitability of the nerve was ascertained by touching it with the electrode of a DuBois-Reymond induction coil, connected with a one-cell battery, the secondary coil or bobbin being moved up or down as required. The farther the bobbin is removed from the primary coil the weaker the current,—*i.e.*, twelve centimetres equals a weaker current than six centimetres.

It was noticed in every instance that a stronger current was required to excite a con-

traction of the muscle after a crystal was placed upon the nerve than before. Also, if the electrode was applied to the distal side of the crystal, it required a much stronger current to excite a reflex movement than before. So it is evident that the power of conduction in the nerve is very considerably decreased. This, of course, could be due to two things,—either to the physiological action of the drug upon the nerve by imbibition, or to destruction or disintegration of the nerve-fibre by direct action. That it was at least in part due to the latter is not improbable, for it was observed that when the crystal was placed on the nerve the surrounding tissues appeared bleached; however, the macroscopic appearance of the nerve itself was not changed. (See Experiments 14 and 15.)

When the cord was laid bare and treated in a similar way, the same result followed with respect to conduction of current,—*i.e.*, it passed the point of contact of the crystal only with difficulty or not at all. But when the electrode was placed in front of the crystal, the fore extremities contracted, and when placed back of the crystal, the hind extremities contracted. No doubt one factor in this obstruction to the current was the direct *local action* of the drug on the part, as suggested above; but there can be little doubt also that it was in part due to the *physiological* action of the drug. (See Experiments 16 and 17.)

It was noticed that immediately after the crystal was placed upon the cord there were tremors or clonic contractions of the front and hind legs. These phenomena were of course referable to the same cause as noted above when the drug was given hypodermically.

When a crystal of the valerianate was placed on the exposed brain there was at first considerable excitement; however, no more probably than would be produced by an irritant. The drug was of acid reaction, and would thus act. After a little time the animal became quiet, and was not easily disturbed, but when aroused moved around with difficulty. Later, it lay in a stupid condition, thus manifesting the depressant action of the drug upon the brain. (See Experiment 18.)

For a record of the experiments and conclusions see the following:

Experiment 1.—Frog healthy.

- P.M.
 1.35. 10 minims of a 1 per cent. solution administered.
 1.38. Clonic contraction of muscles over whole body.
 1.50. Frog in a stupor and reflexes dulled.

P.M.

- 2.10. Fore legs drawn close under the belly, and reflexes absent in them. Occasional kicking out with hind legs.
2.30. Frog still in a torpid condition; reflexes dulled.

Experiment 2.—Frog healthy.

P.M.

- 1.00. 10 minims of a 5 per cent. solution administered.
1.05. Tetanic convulsions of all the limbs, more noticeable in fore than hind legs; reflexes good.
1.15. Fore legs paralyzed and drawn close under the body; reflexes still good in hind limbs.
1.30. Reflexes good in hind legs.
2.30. Reflexes in all legs, but better in hind legs.

Experiment 3.—Frog normal.

P.M.

- 1.30. 15 minims of a 1 per cent. solution administered.
1.33. Clonic contractions of whole body.
1.45. Reflexes good.
2.30. Frog active; exalted reflex.
One day later. Frog living and apparently healthy.

Experiment 4.—Frog normal.

P.M.

- 1.20. 15 minims of a 10 per cent. solution administered.
1.25. Clonic spasms anteriorly and posteriorly; reflexes good.
1.35. Reflexes in hind extremities still good. Paralysis apparent, and all sensation lost in right fore foot.
1.40. Fore legs paralyzed.
2.15. Frog dead.

Experiment 5.—Frog normal.

P.M.

- 1.50. 60 minims of a 10 per cent. solution administered. When placed in water the frog lies flat on its belly.
2.00. Lying more on left than right side; pushes itself wearily around. Legs on left side seem paralyzed.
2.10. Slight efforts made by right fore leg. When pricked manifests no signs of pain.
2.30. Frog dead without a struggle.

Experiment 6.—Medulla and brain destroyed.

P.M.

- 2.55. 15 minims of a 1 per cent. solution injected, followed by very insignificant clonic contractions.
3.20. Reflexes good, probably exaggerated; fore parts more affected than the hind parts; fore legs drawn closely under the belly, and reflex very good in hind legs.
5.15. Exalted reflex in hind legs; none in fore legs.

Experiment 7.—

A.M.

- 9.40. Medulla destroyed.
The time of reflexes was noted by dipping the hind legs of the animal in acidulated solution.
10.10. Reflex in 1 second.
10.15. Reflex in 2 seconds.
10.20. Reflex in 2 seconds.

A.M.

- 10.22. 5 minims of a 2 per cent. solution injected (small frog).
10.26. Reflex in 6 seconds.
10.30. Reflex in 9 seconds.
10.35. Frog dead.

Experiment 8.—

A.M.

- 9.45. Medulla destroyed.
10.10. Reflex in $1\frac{1}{4}$ seconds.
10.15. Reflex in 3 seconds.
10.20. Reflex in 5 seconds.
10.23. 10 minims of a 2 per cent. solution injected (large frog).
10.27. Reflex in 3 seconds.
10.30. Reflex in 6 seconds.
10.35. Reflex in 7 seconds.
10.45. Reflex in 9 seconds.
10.47. 10 minims more solution injected.
10.50. Reflex in 9 seconds.
10.55. Reflex in 10 seconds.
11.00. Reflex in 11 seconds.
11.15. Reflex in 12 seconds.
11.30. Reflex in 15 seconds.
11.45. Reflex in 15 seconds. Feeble response.

Experiment 9.—

P.M.

- 1.30. Medulla destroyed.
1.45. Reflex in 10 seconds.
1.50. Reflex in 13 seconds.
1.55. Reflex in 14 seconds.
2.00. Reflex in 20 seconds.
2.02. 10 minims of a 2 per cent. solution injected.
2.08. Reflex in 85 seconds.
2.15. No reflex in 250 seconds.
2.55. Frog dead to all nerve-stimulus. Heart continues to beat long after sensation is lost, so the drug seems to be a nerve-poison.

Experiment 10.—

P.M.

- 2.10. Medulla destroyed.
2.45. Reflex in 25 seconds.
2.50. Reflex in 25 seconds.
2.53. 10 minims of a 2 per cent. solution injected.
2.57. Reflex in 36 seconds.
3.08. Reflex in 28 seconds.
3.20. No reflex in 100 seconds.

Experiment 11.—

A.M.

- 10.30. Cerebrum destroyed.
11.00. 10 minims of a 2 per cent. solution injected.
11.30. No symptoms manifested in half an hour.

P.M.

- 2.05. 10 minims more solution given; no symptoms.
2.20. More of the drug administered without any apparent effect.
One day later. Frog still alive, and reflexes very active.

P.M.

- 1.40. 60 minims of a 2 per cent. solution injected; no tremors followed, but the frog made an occasional desperate jump.
2.10. Frog dead.

Experiment 12.—Brain destroyed.

P.M.

- 2.00. 30 minims solution injected; this amount killed a frog with medulla destroyed in about half an hour.

The hypodermic needle was introduced under the skin in right side, and in a few moments afterwards the frog began to move around towards the right, and showed slight signs of twitching. Probably the brain was not wholly destroyed, and this may account for the symptoms.

- 2.10. Reflexes good.
2.50. Reflexes good.
3.15. Reflexes still good, but no other symptoms worth noting were observed.

Two days later. Frog still living; reflexes good. The experiment shows that the drug will not kill in the same time or with the same amounts when the brain is destroyed as when the medulla is destroyed.

- 1.35. 60 minims of a 2 per cent. solution injected into the peritoneum.
1.40. Reflexes considerably dulled.
3.20. Reflexes still very dull.

Experiment 13.—

P.M.

- 2.08. Medulla destroyed.
2.15. Blood-vessels of one hind leg ligated; reflexes good in both legs.
2.20. 5 minims of a 2 per cent. solution injected into the peritoneum; reflexes good in both legs.
2.25. Reflexes good in both hind legs.
2.30. Reflexes good in both hind legs.
2.40. Reflexes slightly impaired in both hind legs.
2.53. Reflexes gone in both hind legs.

In the following experiments the current used was that of the DuBois-Reymond induction coil and one-cell battery. The number of centimetres named indicates the distance between the primary and secondary coils.

Experiment 14.—

P.M.

- 3.00. Medulla destroyed.
3.08. Secondary coil removed 27 centimetres from primary gives minimum contraction of muscles.
3.18. 32 centimetres gives minimum contraction.
3.20. Crystal of the valerianate laid on the exposed sciatic nerve.
3.30. 18 centimetres gives minimum contraction.
3.35. Another crystal laid on the exposed nerve. The crystal seems to bleach the muscle where it touches, but no change appears in the color of the nerve. When the electrode is applied below the point where the crystal is placed upon the nerve, reflex action cannot be excited even with a very strong current.
3.45. Contraction obtained only when the bobbin is removed 12 centimetres.
4.00. 12 centimetres gives minimum contraction.

Experiment 15.—

A.M.

- 9.40. Medulla destroyed and sciatic nerve exposed.

A.M.

- 9.50. 28 centimetres gives response.
9.55. 30 centimetres gives pretty active contraction.
10.00. 31 centimetres gives contraction.
10.05. 32 centimetres gives active contraction.
10.10. Crystal of the valerianate laid on the exposed sciatic nerve of one leg. Bleaching of the tissues was observed, as noted above.
10.15. 13 centimetres gave a feeble response on the side upon which the crystal was placed, while 32 centimetres gave active contraction on the other side.
10.20. Another crystal placed on the exposed nerve.
10.30. 34 centimetres gave well-marked contraction on right side, but full strength of the battery gave no contraction on the side upon which the crystal was laid.

Experiment 16.—Medulla destroyed.

P.M.

- 1.45. Spinal cord laid bare.
1.55. Reflex in both fore and hind extremities, both on mechanical and electric irritation.
1.58. Crystal of the valerianate placed on the cord, followed by (1) tremors in the fore limbs; (2) tremors in the hind limbs.
2.10. Another crystal placed on the cord.
2.15. Electricity applied to cord.
When the electrode is placed on anterior part of the cord the fore limbs respond, but when placed behind the crystal only the hind limbs respond,—i.e., the current was not conducted through the part of the cord where the valerianate was applied. Before the valerianate was laid on the cord 22 centimetres caused muscular contraction; afterwards the secondary coil had to be pushed up to 12 centimetres to produce contraction.
2.45. 10 centimetres gives response.
2.50. 8 centimetres gives contraction in the fore legs.
6 centimetres gives contraction in the hind legs.

Experiment 17.—

P.M.

- 2.00. Medulla destroyed and cord exposed.
2.10. 35 centimetres caused minimum response.
2.15. 26 centimetres caused response; crystal of the valerianate placed upon the cord; discoloration of the tissues marked.
2.20. 20 centimetres gives response.
Tremors occurred in the hind limbs after placing the crystal on the cord. The current of electricity does not seem to be able to pass through the part of the cord upon which the crystal has been placed.
2.38. 16 centimetres gave contraction in hind legs when the electrode was applied to the posterior part of the cord, and 17 centimetres gave contraction in fore legs when applied to the anterior part of the cord.
2.40. Another crystal of the valerianate placed on the cord.
2.50. 11 centimetres gives contraction of the anterior limbs; 12 centimetres gives contraction of the posterior limbs.
3.05. Frog only feebly responds in anterior limbs to full power of the battery.

Experiment 18.—

P.M.

225. Brain exposed.
230. Crystal of the valerianate laid on the exposed brain.
235. Frog jumping around considerably; no more, however, than might be produced by an irritant.
245. Another crystal placed on the brain.
255. Animal gives one or two kicks, but for the most part remains quiet and is not easily disturbed.
305. Frog seems scarcely able to move around.
Another crystal laid on the brain. Frog remains stupid.

The drug was obtained from Rosengarten & Bros., and was of acid reaction. This probably gave rise to its irritant action.

The conclusions arrived at are as follows:

First.—With the exception of the convulsions, the drug is a universal depressant to the nervous system.

Second.—The convulsions are of spinal origin.

Third.—In small doses the drug probably stimulates the cord.

Fourth.—In large doses the drug depresses the cord.

Fifth.—Locally the drug is a universal depressant.

REMARKS ON THE THERAPEUTIC VALUE
OF MANACA, JAMAICA DOGWOOD,
AND EUPHORBIA PILULIFERA,
VIBURNUM PRUNIFOLIUM.

BY ALLAN S. PAYNE, M.D.*

I CONSIDER the *Franciscea uniflora*, manaca, one of the very best therapeutic remedies we have in cases of rheumatism, rheumatic gout, and eruptive diseases of syphilitic origin. I have seen many cases of chronic, subacute, and inflammatory rheumatism and syphilitic eruptions readily yield to the administration of the fluid ext. manaca, in doses ranging from 8 to 20 drops three times a day. I have been prescribing for the last eight years in my practice the manaca, and could, if I had the time, report numerous cases where its exhibition was of unquestioned value in inflammatory, subacute, and chronic rheumatism. In secondary and tertiary syphilis its action has been more prompt and more satisfactory to me than my old favorite remedies, iodide of potassium and sarsaparilla, or the bichloride hydrargyrum either. But as I

gave my views freely some time ago through the columns of the THERAPEUTIC GAZETTE as to the value of the fluid extract of manaca, I will now only say in my opinion it still holds its own, and pass on to the consideration of *Euphorbia pilulifera*. I have not had as much experience with this remedy as I could wish, having only prescribed it in three cases of spasmodic asthma, one case complicated with bronchial irritation.

Peter I., carpenter by trade, age 46, came to me in September, 1886, suffering with spasmodic asthma and bronchial irritation; complained of a sense of great weakness for want of breath; could not do any work at his trade; was always hale, hearty, and strong until during the war was confined in camp on the banks of the Appomattox; ever since had been subject to these asthmatic attacks. He was weaker, and considered this the worst attack he has ever had; had been longer unable to work than ever before. His complexion was sallow, skin dry and felt harsh to the hand, tongue coated with a thick whitish fur, urine scanty and high-colored. R 5 grs. sulph. quinine, night and morning; gave him sub. mur. hydr., gr. x; ext. coly. comp., gr. x; pulvis ipecac., gr. i; ol. cajuput., gtt. ii; divide into two powders; take one at 3 P.M., the other at bedtime; next morning teaspoonful *Carlsbad salts* in glass cold water; fluid ext. *Euphorbia pilulifera*, 30 to 50 drops *pro re nata*. He came to my office day before yesterday for me to prescribe for his wife and daughter. He says he is stronger and better than he has been since the war, and that the little black drops cured him.

I. P., farmer and fox-hunter, has been subject to attacks of asthma since childhood, the attacks getting worse; is 27 years old; has tried a great many remedies without any permanent benefit; would be well and hearty if it were not for these attacks. R 30 to 60 drops *Euphorbia pilulifera pro re nata*. Reports to me as having experienced great relief; has not had any attack this winter, although he has fox-hunted as much as usual; thinks the black drops cured him.

The other case I have not heard from; think he is also better, or I assuredly would have heard from him. This patient lives in an adjoining county. I have found the *Piscidia erythrina* (Jamaica dogwood) a valuable remedy in nervous persons, who cannot bear opiates, and in cases where you desire to promote an increase of the secretions rather than check them. The Jamaica dogwood seems to ease pain, promote refreshing sleep, and, if

* Late Professor of Theory and Practice of Medicine in the Southern Medical College, Atlanta, Georgia; Hon. Fellow Virginia Medical Society, etc.

repeated, will gently move the bowels and increase the flow of urine. These properties render it an exceedingly valuable preparation in persons of peculiar nervous cachexia.

Viburnum Prunifolium (Black Haw).—The fluid extract of viburnum prunifolium is a valuable auxiliary in the field of gynecology. In looking over the literature of this valuable drug I find it ample, so much so that I deem it unnecessary to say anything more in its favor than to express the opinion that those persons who believe it inert or worthless in a large number of diseases incident to the female organs of generation have made their experiments with worthless preparations of this drug. I have used the infusion made from the root of the black haw, but it is by no means as decided in its therapeutic action as the fluid extract. Its properties seem to be anodyne, tonic, and alterative, when administered per orem in sufficient doses. Its virtues are by reflex action or through the nerve-centres conveyed to the female organs of generation, and exert upon these important organs a benign influence not excelled by any drug with which I am acquainted. From its anodyne, tonic, and alterative action it has a wide range of adaptability in the field of gynecology. I myself have used the fluid ext. of viburnum prunifolium in anæmic amenorrhœa, dysmenorrhœa, membranous dysmenorrhœa, and threatened abortions many, many times. I successfully treated three cases of membranous dysmenorrhœa in Atlanta, Georgia, at the same time and in the same hotel. Two cases were residents of Atlanta, the third a young lady from the far Northwest. And last summer a young lady from the valley of Virginia fell under my charge. I mention these four cases particularly because they were unusually severe cases, had been under the care for a long time of several able physicians, and their lives had become, as they expressed it, a "*misery to them.*" Of course in my practice of nearly half a century I have met many cases, moderate cases of simple and membranous dysmenorrhœa. My treatment in these four severe cases of membranous dysmenorrhœa was, keep bowels soluble with Carlsbad salts, and take the following:

R Fluid ext. phytolacca,
Fluid ext. cimicifuga racemosa, aa ℥iiss;
Vinum colchicum sem., ℥iiss;
Fluid amm. guiac., ℥v. M.
Sig.—30 drops t. i. d.

Just before the expected molimen take:

Camphor., gr. x;
Pulv. Doveri, gr. x;
Ext. hyoscyami, gr. x.
Fiat 10 pills.

Two pills every two hours until pain ceases, then fluid ext. viburnum prunifolium 60 drops t. i. d.

To be continued until next molimen occurs. Plan of treatment to be continued until there is freedom from pain and an increase of the monthly discharge.

In a case of threatened miscarriage, the first thing for a woman to do is to go to bed and assume the horizontal position. The next is to get her bowels opened by a mild aperient, such as the Carlsbad salts, assisted in its action by an injection composed of mild ingredients. If there is pain after her bowels are opened, throw into the rectum 40 drops tinct. opii in a tablespoonful of starch and warm water, *tepid* water, and take a teaspoonful of viburnum prunifolium t. i. d. If the patient has been in the habit of miscarrying, whenever she feels the slightest pain she should go to bed, throw into her rectum the starch and laudanum injection, and take a dose or two of the viburnum.

In some cases of membranous dysmenorrhœa the practitioner will also find persistent leucorrhœa. In these cases give three times a day—

R Fluid ext. buchu,
Mur. tinct. ferri, aa ℥iiss. M.

S.—Teaspoonful morning, noon, and night in wine-glassful of water. Hot-water injection at bedtime, using hot water in large quantities, and an occasional dose of viburnum.

As soon as leucorrhœa is relieved withdraw the iron and buchu, and give the viburnum t. i. d. If patient is of scrofulous cachexia, give 10 drops syr. ferri iodide t. i. d. in combination with the viburnum.

I will briefly record a case or two of miscarriage that plainly show the value of therapeutic medication. These cases are to be divided into two classes: the first where there has been pain with muscular contraction, but no rupture of the membranes has occurred, and the fœtus is alive; the second where the membranes are ruptured or the fœtus is dead. I have already sketched my plan for preventing miscarriage; I will now name my remedy. My remedy is "*hydrarg. cum creta.*"

I have found by long and ample experience that 10 grs. hydrarg. cum. creta will in all cases of a dead fœtus, or ruptured membranes retained in utero, or in many cases of protracted labor, act with more *promptness, power,*

and *certainly* than all the preparations of ergot or any other emmenagogues that I have ever crossed in a large female practice reaching nearly a half-century. I will state one or two cases. I could give many had I the time to do so.

Mrs. R., age 30, of nervo-bilious temperament, mother of three living children, in my absence from home four days ago, in the opinion of an old midwife, had a miscarriage. On my return home her husband came for me. When I reached her house I found her bathed in a cold, clammy perspiration, pulse 120, weak, unable to sleep, no desire for food, with a feeling of general *malaise*. I found the midwife in the room. To her I said, "Well, did you see the dead child and the after-birth?" "Yes, sir." "You think everything has come away, and the womb has cleaned itself well?" "Yes, sir." "Well, I must tell you for once you are mistaken, and I will soon show you that you are mistaken." I gave Mrs. R. 10 grs. hydrarg. cum creta, and, with watch in hand, took my seat to await developments. In just sixty minutes she had a movement of the bowels, accompanied with a strong uterine pain, and lo! the dead fetus, about two and a half inches long, and the after-birth were both expelled by the single pain. Great was the old woman's astonishment when she saw she had mistaken "*clots*" of blood for the dead embryo and its membranes. This was not the first nor the last time I have seen this mistake made by the aged midwife. Gave Mrs. R. dose of Carlsbad salts in the morning, directed her to bathe her abdomen and uterine region with a strong infusion of eupatorium perfoliatum; inject hot water, with small quantity of chloride of lime in it, night and morning, and give fluid ext. viburnum prunifolium t. i. d., to be continued four days; convalesced rapidly.

S. B., mother of seven living children, is 42 years of age; has never before had any trouble in her confinements. I saw her the fifth day after her confinement, found her bathed in cold, clammy perspiration, pulse 110 and weak, unable to eat or to sleep, feels bad all over; had taken a dose of castor oil two days ago, but had no action; urine high-colored and scanty. Gave her 10 grs. of hydrarg. cum creta; in just two hours she had a movement from the bowels, accompanied by a strong pain, as strong as a labor-pain, and there came away a piece of after-birth the size of a silver dollar. Ordered her dose of Carlsbad salts next day; bathed stomach, over the womb, twice a day with a strong hot infu-

sion of the eupatorium perfoliatum; washed out the vagina with hot water, with a small per cent. of chloride of lime in it, and gave fluid ext. viburnum perfoliatum t. i. d., to be continued five days.

A little over twelve months and I was called to this same woman on the fifth day after her confinement, found her in the same condition, and brought away again a piece of after-birth the same size by same remedy. Two years after this, and it was in her last confinement, I had to ride ten miles to see this same woman, on the same fifth day after confinement, and found her in the same condition. My treatment was a duplicate of my first two visits in every respect. Both of these women are living, have passed the age for child-bearing, and are hale, hearty women.

Here the question naturally arises, Why is the hydrarg. cum creta, a mild aperient, such a powerful promoter of uterine contraction? There undoubtedly is great sympathy between the muscles of the rectum, particularly the levator ani muscle, and those of the womb. The muscular contractions of the womb and its expulsive efforts are *nil* unless assisted by the co-ordinate action of the levator ani muscle. The *modus operandi* I conceive to be this: The crude mercury in the hydrarg. cum creta is a powerful, the most powerful known promoter of peristaltic action of the intestines. It exerts its effects through the *whole tract*, and per consequence, produces full, free, harmonious contraction of the uterine and intestinal muscular systems. Both of these muscular systems, acting in harmony and in unison, can exert an expelling force, which, "singly and alone," neither one is capable of. Drastic purgatives, as podophyllin, are not promoters of harmonious action between these muscular systems, but rather the reverse. I do not wish to be understood as saying that the hydrarg. cum creta is the only remedy or the only means of producing harmonious action between the intestinal and the uterine muscular systems, but I do say it is the most prompt, powerful, and certain promoter of concert of action between these two muscular systems. On the other hand, I have myself produced this same concert of action by different remedies and different procedures, and at different times, when contractions of the uterus are irregular. When vagina is hot and dry, I order 2 grs. antimonii et potassii tartras in 6 ozs. of water, tablespoonful every fifteen minutes, until emesis is produced. This will bring on harmonious action,

and often the child will be speedily born. Then, again, I have known when bowels were constipated, and the pains not regular or effective, by throwing into the rectum a salt-water injection, and by cleansing out the overloaded bowels, the equilibrium of the system would be restored, the two muscular systems brought in harmony, with the best of results. At another time $\frac{1}{4}$ grain sulph. morphine has accomplished the same result. Again, once or twice or three times in my long professional career I have found the patient suffering severely, but as soon as I arrived, and she knew it, she would become so well satisfied, so well contented, that she would become entirely free from pain, until, after a long, fair trial, I have had to make them uneasy by telling them I must go home, as I had stayed as long with them as I could do; pretend to start, to be called back, and labor completed in fifteen minutes. Again, I have succeeded by making patient mad, mad as a hornet, before this harmonious action would be developed, but I never lose sight of the fact that I want the rectum to *assist*.

The patient will often tell you that her bowels are sufficiently open; but as the child's head passes the superior strait, it is pressing before it a mass of hardened feces: this will protract the length of the labor, and cause her longer and greater suffering. Some gynecologists say, do not interfere with this, leave it entirely to nature, but I say, grease your finger, and inadvertently slip it into the rectum, and slowly and carefully pick out these masses; the labor will be shorter, easier, and you may prevent a vesico-vaginal fistula or a ruptured perineum by so doing.

(To be continued.)

METEOROLOGY.

By A. COMSTOCK, M.D., TOLEDO, OHIO.

IN the matter of climate, as related to the medical profession, *guessing* is unsatisfactory, unscientific, and must be excluded. The advantage of climatic hygiene is recognized, and the necessity, though tardily admitted, must in many cases become an ultimatum. The fatal error, compounded in part from the indecision of the doctor and the patient, lies in the direction of inactivity and delay. In this country we have been particularly unfortunate till of late, because an ocean voyage lay between us and the springs or mountains or dry atmosphere

found in parts of Europe, and our own resources were comparatively unknown. When not unknown they were largely inaccessible, for but recently have we been able to reach the Adirondacks, the mountains of North Carolina, the soft air of Florida, or the foothills of California and Colorado. There is a great variety of condition and adaptability to be secured, and, if properly investigated, it will soon be learned and appreciated.

Much has been written of late by medical authors, and much generalizing, together with much expansion of discretion. The tendency is to claim too much, and present the attractions of some thermal spring or lime-grove as a pain-killer of the widest latitude, or give it the status of a patent nostrum. The factors which go to make up the issue are the condition of the patient and the quality of the climate. So long as in the history of evolution man is an air-breathing animal, and so long as houses are badly constructed, and towns located for convenience of commerce regardless of anybody's lodging apartments, light, heat, drainage, and breathing space, so long will life be cheap and money dear. The great mass will continue to risk life and recklessly lose it, but some desire life, and will make the fight for it. In a monograph by Dr. William, in last July's *Sanitarium*, on "The Climatic Treatment of Phthisis," he comments as follows as to his notion of a first-choice resort in such cases: "It should possess a pure water-supply and adequate drainage; it should be of a dry and porous soil, and should be favorably situated with respect to neighboring heights and marshes and prevailing winds. It should be equable in temperature, and possess the maximum of pleasant weather. It should not be so hot as to be enervating, nor so cold as to prevent out-door exercise and proper ventilation of houses. It should afford plenty of amusements; it should not be crowded with consumptives, and it should be sufficiently unfashionable to admit of hygienic dress; should be sparsely populated and newly settled." To be out of doors, to be entertained, to be properly clad and fed, and sleep—for one-third of the time we must be in bed—are the staples. Climate that will do for some conditions and stages of phthisis will not be best for others, and that which will quiet and subdue a neurotic lesion may not be the place for a defective kidney; as also is the reverse true. A malarial diathesis must seek an environment that doubtless would not be suited to the victim of rheumatism.

What we require, in order to guide us and

advise our patients, is the *detail* of climatic symptoms, as we are presumed to know the symptoms of the case before us, and we desire that, rather than the opinion of any one man of any one locality in such cases, since we assume the responsibility.

Fully appreciating the justice of this line of thought, some of the profession in Colorado have been urging for years a systematic report from which an intelligent inference may be drawn. During the session of the Legislature preceding the present one, a charter was granted to the incorporators of the "Colorado Meteorological Association." Being without an appropriation, a voluntary effort was made by some of the medical men, aided by members of other scientific bodies, to fairly represent some varieties of climate in this interesting region. The work has been in progress for nearly one year, and includes observations from about twenty-five places. Some of the points are supplied with all the most approved instruments to note direction and velocity of wind, barometric and thermometric conditions, precipitate of moisture either by rain or snow, and humidity of the atmosphere, portions of the day when cloudy or clear sky is observed, etc. In the case of others, barometers and hygrometers are absent.

Where the United States signal stations are, observations are taken five times per day, and

at all points not less than three,—namely, at 7 A.M., 2 P.M., and 8 P.M., from which the average mean is derived. The reports are sent to headquarters for each week, from which the monthly publications or bulletins are compiled. The present Director of Observations is F. H. Loud, Professor of Natural Science at the College of Colorado Springs. These reports will increase in value as an interval of time and wider observation follow, for the selection of points will be noted as well taken by reference to the chart of Colorado.

The elevations of the different observatories are in feet as follows: Alma, 10,300; Cañon City, 5344; Colorado Springs, 5992; Denver, 5294; Dodge City, Kansas, 2517; Durango, 6520; Fort Collins, 4900; Fort Lewis, 8500; Georgetown, 8500; Glenwood Springs, 5200; Golden, 5665; Hugo, 5068; Idaho Springs, 7500; Las Animas, 3899; Longmont, 5000; Montrose, 5825; Monte Vista, 7200; Pandora, 8700; Saguache, 7750; Santa Fé, 7026; Silverton, 9400; Trinidad, 6070; Westcliffe, 7800; Pike's Peak, 14,131.

The report for the month of November, 1886, is here appended to indicate the character of work and figures for that time.

The following table contains statistics of temperature (T) and rainfall (R) for the month of November in fifteen years:

Comparison of Different Years.

Denver.				Colorado Springs.				Denver.				Colorado Springs.			
Year.		T.	R.	T.	R.	Year.		T.	R.	T.	R.	Year.		T.	R.
1872.....	33.7	0.69	30.4	0.26	1877.....	35.2	0.73	30.9	0.22	1882.....	37.4	0.71

MURIATE OF PILOCARPINE IN URÆMIA.

BY A. D. BUNDY, M.D., ST. ANSGAR, IOWA.

THERE is nothing new either in the drug or in the use of the same in this short communication. But I wish to emphasize its great use and efficiency in cases of acute nephritis, where the suppression of the urine is nearly complete, and in which the patients are in extreme peril unless the kidneys can be temporarily relieved by prompt and free sweating. I know no remedy so efficient, prompt, and free from danger as pilocarpine. I have used it hypodermically in children with the best results, and no sign of injury. There are times in every practitioner's experiences when to have such a remedy at hand, and at the same time the boldness and knowledge to use it, is to tide a patient over a critical place until other remedies and means can be used to follow up its beneficial effects. One of such occasions is such as I have mentioned. When convulsions and coma have possession of such cases, time is almost wasted in pouring drugs into the stomach, even were it possible, or even injecting the same per anum. Pilocarpine, according to my experience, which is quite large, has done me and my patients royal service. It ought to be in the possession of every physician. The knowledge that it is used but little in the country is my reason for writing this.

USE OF THE ABDOMINAL BANDAGE IN THE SECOND STAGE OF LABOR.

BY CHEVES BEVILL, M.D., WINFIELD, ARK.

IN the September number of the THERAPEUTIC GAZETTE, 1886, page 599, is an article headed as the above, by Dr. J. Wesley Welker, of Stromburg, Neb. I have looked closely in every number since that for some one to say something on the same subject.

I hope that Dr. Welker will not be offended at what I say (such questions strictly belong to obstetric journals rather than the GAZETTE). I am satisfied that many young physicians who have read Dr. Welker's article will be badly disappointed in their expectations by the use of the bandage.

I have used the bandage regularly ever since April, 1877, and have found great benefit by its use in one class of troubles,—i.e.,

anterior or lateral obliquity of the uterus. Meigs used it in his practice years ago. Cazeaux, in his great work on obstetrics, recommends it in cases of obliquity. On page 412 of the *American Journal of Obstetrics*, April, 1880, is to be seen an account of an "elastic bandage" used by Drs. Morton and Marcy. These gentlemen used it, and speak in high terms of its use in holding the "fundus down," and state that it "was a part of the obstetrician's armamentarium in the Middle Ages."

The main thing I wish to speak of is that Dr. Welker's cases were taken indiscriminately, without seeing whether it was necessary to use the bandage or not. Every physician of any experience has found scores of such cases as the doctor refers to. Now, if these cases are noticed closely, they will be found to be only natural cases of labor, not one word said about any obliquity of the uterus existing. I have seen many cases of labor that were completed in as short a space of time as is here spoken of. If the doctor had cited cases that had been in labor for several hours, and in which the os would turn back in the hollow of the sacrum when the pains came on, there would be more encouragement for the young physician to use the bandage.

I have used it in the second stage of labor in four cases in the last ten months, where the uterus would tilt over anteriorly, and had continued to do so for two or three hours before I applied any bandage. These cases were all women who had borne several children, and their abdominal muscles were relaxed, and this bandage was a great help to them in giving support to the back and abdominal muscles, and keeping the os in the line of the pelvic straits until the child's head would become engaged in the straits.

I wish all physicians would use the bandage in such cases. It would save the mother much pain and hasten labor, and would save the child in some cases. But it will not, according to my observations, work in every case as well as in the cases above referred to.

I saw a case a year ago where a child's life was lost, I am satisfied, by not using the bandage. The forceps were applied, and the child's head badly bruised by them. The physicians in charge said that the os would turn back in the hollow of the sacrum, and that the os was fully dilated. In such cases use the bandage, or any other contrivance. But let us not make doctors think that it will do in all cases as well as in such as above referred to.

BROMISM.

THE series of phenomena known as bromism must be familiar to almost every active practitioner of medicine. Although, therefore, mild poisoning by the salt is very frequent, really serious symptoms are rare, and literature is almost bare of instances of death fairly attributable to poisoning by bromide of potassium. The only case in which death has been recorded as due to acute poisoning by the bromide of potassium is one reported by Küssner, in which a patient having been ordered to take daily 1 to 2 teaspoonfuls of a solution containing one hundred and fifty grammes of the bromide of potassium, took a teaspoonful hourly until during the second day, when he had used about half the mixture. Death occurred through the failure of the heart. We have known half an ounce of the bromide to be taken at a single dose with no evil results, and it seems very doubtful whether it would be possible to take life by a single dose of this salt, as any very large amount would be very apt to produce vomiting and rejection of much that had been swallowed. Cases of fatal poisoning by the

continuous use of the drug are also excessively rare.

Dr. Hameau, of Bordeaux, reported in the *Journal de Médecine* of Bordeaux, March, 1868, the case of a young woman, aged 22, who had taken about four and a half pounds of the bromide of potassium in ascending doses during a treatment of ten months, and who, whilst in a condition of cachexia, with yellowish skin, a copper-colored exanthema upon the forehead, colic, gastralgia, insomnia, etc., was taken with delirium, profuse sweats, great prostration, followed by death in four days.

Dr. Anton Eigner, in the *Weiner Med. Presse*, Nos. 25 to 34, 1886, reports the case of a woman who took two and a half kilogrammes—about five pounds—of bromide in less than a year. On the 27th of September the woman was quiet, with pupils normal, except that they were slightly unequal, with the tongue heavily coated, gums swollen, some inflammation of the mucous membrane of the nose, gums, and teeth, and a heavy odor of bromism upon the breath. There was also a marked eruption of acne, distinct lessening of the sensibility of the gums, tongue, and fauces, general weakness, and much pain in the forehead. When movements were attempted with the hands there was a distinct tremor, but the woman was still able to walk, though with some tendency towards staggering. Some hours later excitement came on and soon passed into delirium, the patient getting out of the bed, wandering around with short steps, feeling for something with her trembling hands, suffering from hallucinations of sight and hearing, and complaining bitterly that she was being poisoned. This condition lasted, with some ameliorations and exacerbations, from the 28th of September until the evening of the 1st of October, when death occurred. At the autopsy, pronounced bronchitis and lobular pneumonia of the lower lobe of the right lung were found; but the brain, meninges, and spinal cord revealed no abnormality even to the microscopic examination. It is very probable that the excessive amount of bromide of potassium taken had in this case something to do with the death, by predisposing or possibly producing the bronchitis and the pneumonia, yet, although the mental disturbance is affirmed to have preceded the coming on of the lung-trouble, doubt must remain whether the case ought to be considered one simply of death from bromism. It has not been long since it was shown in an editorial in this journal that in some cases the cerebral symptoms overshadow the ordi-

nary signs of pneumonia. It seems probable that in the case reported by Dr. Eigner the pneumonia was not detected at its onset. The delirious excitement is more like the ordinary cerebral nervous symptoms of the so-called cerebral pneumonia than it is like the apathy of depression, the gradual burying in oblivion of all the cerebral functions, which is characteristic of typical bromide-poisoning.

PATHOGENETIC THERAPEUTICS.

ON the evening of February 7, Dr. Harold C. Ernst, of the Medical School of Harvard University, read before the Philadelphia Academy of Surgery an account of the experimental research upon rabies which he has made during the past six months. The report bore upon its face every evidence of careful, clean-cut, scientific work, and, so far as one can judge from the hearing of a paper, was conclusive in its results.

Dr. Ernst did not use the virus of "street rabies," but one which he obtained from the laboratory of Pasteur. His labors seem to prove that this Pasteurian virus, when introduced either hypodermically or under the dura mater, causes a definite disease, with a period of incubation averaging from seven to twelve days, but in very rare cases as short as three, and in others as long as twenty-three days; that it especially abounds in spinal cords of animals poisoned with it; that it is capable of preservation for many months by the freezing of the cord, but loses its intensity by being slowly dried; and that if an animal which has been poisoned by the active virus be subsequently inoculated a number of times by impaired or weakened virus, fatal illness is avoided. This, of course, does not prove that the inoculation of this virus would be effective against true street rabies, because it still remains a matter of doubt whether or no the Pasteurian virus is that of true rabies, although the resemblance of the diseases produced by the Pasteurian virus to street rabies and the assertions of Pasteur, of course, render highly probable that his virus is a modified street rabies virus. Dr. Ernst quoted the work of M. D. Frisch, of Vienna, as confirmatory of his own results and of those previously obtained by Pasteur. At this writing the full memoir of M. de Frisch has not been published, and the Vienna correspondent of *La Semaine Médicale* asserts in the number which has just reached this country, that although

M. de Frisch found that the Pasteurian virus would protect the animal from itself, it failed in every case in which the original poison was taken directly from a case of street rabies. It is perfectly evident that the scientific battle now rages just about this point, and that the Pasteurians, before their results can be accepted, must prove that the disease produced by the Pasteur virus is active against true street rabies. It is a most unfortunate circumstance that the loose and excessive talking, and the broken, tumultuous manner of reporting his work, which seems to be inherent to the constitution of M. Pasteur, prevents any one from knowing with certainty where he did get his original virus. We suppose, however, that a great genius, such as M. Pasteur undoubtedly is, can only work in accordance with his own nervous organization, and the world must be thankful for what is achieved.

Out of the uncertainties this truth *appears* to emerge, namely, that an animal which has been poisoned by an active virus can be prevented from sickening and dying by frequent subsequent inoculations with the same virus in a weakened or impaired state of activity. To us this is astounding, because it apparently involves the recognition of a new law or principle in therapeutics! A law or principle which has been previously asserted by various crack-brained practitioners of medicine, whose half-witted condition gave to them that imaginative foresight which the common people attribute to a "natural," but whose complete lack of scientific brains prevented from establishing or even rendering probable their imaginative speculations.

Since the days of Jenner it has been known that the inoculation with vaccine matter will prevent the development of smallpox. The theory has always been that a zymotic disease destroys in the system something upon which it feeds, and thereby protects from a second attack. Vaccination has been supposed to destroy in the human system the sustenance of smallpox virus, and thereby prevent the development of the disorder. In the case of hydrophobia, however, the inoculation is practised after the poison has been received into the system, and during a time when the disease really exists, for it is absurd to suppose that the system is not diseased until symptoms break forth. There must be during the period of incubation a progressive alteration of nutritive processes, which only manifests itself in gross symptoms when it has reached a certain intensity. Is it possible that in the

case of the reinoculation with Pasteurian virus organisms are rapidly developed in the system, which are nearly free from toxic properties, and still have the power of destroying that which feeds the more dangerously active entity? Whatever may be the explanation of this newly-discovered principle or law governing the removal of diseases, the thought at once occurs that its power does not simply apply to hydrophobia, but probably dominates the so-called zymotic diseases, or, in other words, all diseases which are dependent for their existence upon the presence in the blood of an organism. If this be so, the smallpox poison, the virus of scarlet fever, the toxic agent of typhus and typhoid fevers, etc., are to be fought each by itself in an altered form, and the day seems approaching in which in these diseases we shall be able not merely, as at present, to alleviate the symptoms but to strike at the very *fons et origo mali*.

FAITH-CURE.

WE have never discussed the subject of faith-cure in our columns because the matter has always seemed to us outside of the domain of rational therapeutics. Any physician who could be swept off his feet by the torrent which flows so tumultuously, although in a narrow and popular channel, could scarcely be influenced by any scientific discussion of the subject.

We are very glad, however, to call the attention of our readers to a discussion of faith-cure in the *Century Magazine* for the month of March. There are two articles, one by Mr. R. Kelso Carter, which is an apology for believers in the doctrine, and another by the Rev. Dr. Buckley, editor of the *Christian Advocate*, who writes very cogently and sensibly. We quote a few paragraphs from him, and trust that our readers will call the attention of any of their clients who may show symptoms of this madness to the article:

"It is a means of obtaining money under false pretenses. Some who promulgate these views are honest, but underneath their proceedings runs a subtle sophistry. They establish institutions which they call faith-homes, declaring that they are supported entirely by faith, and that they use no means to make their work known or to persuade persons to contribute. Meanwhile they advertise their work and institutions in every possible way, publishing reports in which,

though in many instances wanting in business accuracy, they exhibit the most cunning wisdom of the children of this world. . . .

"The horrible mixture of superstition and blasphemy to which these views frequently lead is not known to all persons. I quote from a paper published in Newark, N. J., in the interest of faith-healing:

"DEATH.—Three of the richest men in Ocean Park, N. J., have died. Faith-healing has been taught in the place, but was rejected by them, so death came."

"CHARLESTON, S. C.—A few years ago the Holy Ghost sent me to preach in that city. But they rejected the gospel and me. A wicked man shot at me and tried to kill me, but God saved me so that I was not harmed. . . . But I had to leave Charleston, and do as the great Head of the Church said, . . . "When ye depart out of that house or city, shake off the dust from your feet." Earthquake, September 1, 1886; one-half the city in ruins. It has a population of about fifty thousand people. Ye wicked cities in the world, take warning! God lives!"

MINERAL SPRINGS OF THE UNITED STATES.

THE number of people freighted with their loads of dollars who travel from these United States yearly to the fountains of healing waters which gush forth from the rocks of Central Europe is not a few. It is to be expected that on a continent which boasts of two great ranges of mountains and also immense masses of every known geological strata, mineral springs would abound. We confess, however, that before looking over the Thirty-second Bulletin of the United States Geological Survey (written by Dr. A. C. Peale, and just issued from the governmental printing-office at Washington) we had little idea of the vast numbers of thermal springs in the United States. It is perfectly plain that the only excuse American physicians have for sending patients abroad, so far as natural waters are concerned, is to be found in our ignorance of the exact constituents of our own native mineral springs, and in the lack of proper hotel accommodations at the springs.

Hitherto the fullest published list of our mineral springs has been that compiled by Drs. William Pepper, H. I. Bowditch, and associates, and published in 1880 in the thirty-first volume of the "Transactions of the American Medical Association." It enu-

merates about 500 localities. In the compilation of Dr. Peale, 2822 localities of mineral springs are mentioned. In the Northern Atlantic States there are 405 localities and 637 individual springs; in the Southern Atlantic States, 371 localities and 1048 individual springs; in the Southern Central States, 1201 localities and 1911 individual springs; in the Northern Central States, 601 localities and 1276 individual springs; in the Western States and Territories, 722 localities and 3949 individual springs; making a total of 8821 springs. But a small proportion of this immense number of waters has been analyzed. Thus, out of the nearly 4000 known mineral springs in the Western States only 132 have been studied by the chemist, and only 18 have been used as health resorts.

The more the subject is examined, the greater is the contrast between our actual knowledge of our mineral waters and the apparent riches of this continent. In Wyoming alone, with its 2246 springs, the larger proportion of them thermal, only 7 waters have been analyzed. It would appear that almost every possible water is represented within the mere limits of the National Park.

THE DIGESTIVE FERMENT OF *CARICA PAPAYA*.

WE have recently had put into our hands samples of Finckler's papoid, which is said to be a digestive ferment prepared from the *Carica papaya*, or papau apple. In order to discover whether this substance is really of any value as a food ferment, we placed it in the hands of Dr. Samuel G. Dixon, who, in the Chemical Laboratory of the University of Pennsylvania, made the following tests of it:

TEST NO. 1.

1 gm. of fresh fibrin.
 $\frac{1}{8}$ gm. of papoid.
 50 c.c. of water.
 Temperature, 90° F.
 Time, 12 hours.
 Result, little or no digestion.

TEST NO. 2.

2 small pieces of coagulated egg albumen, with about 10 times the volume of papoid and 50 c.c. of water.
 Temperature, 80° F.
 Time, 12 hours.
 Result, about $\frac{1}{3}$ of albumen broken up.

This test was continued for twelve hours longer, with little or no additional digestion.

TEST NO. 3.

70 mg. of dried fibrin.
 10 mg. of papoid.
 50 c.c. water.
 4 drops of HCl.
 Time, 6 hours.
 Result, unsatisfactory in the extreme, little or no fibrin broken up.

These tests were sufficiently accurate and careful for practical purposes, and demonstrate the uselessness of any further experimentation with commercial papoid.

AN INVESTIGATION OF PASTEUR'S METHODS.

AMONG the critics of Pasteur none have excited more interest than Von Frisch, of Vienna. He was sent by his government to Paris to learn the details of the method, and on his return he repeated many of the experiments of Pasteur, and has studied the subject of hydrophobia critically. His conclusions from work done during 1886 are embodied in his statement to the Vienna Academy of Sciences, and we abstract them from the *Medicinisches-Chirurgisches Rundschau* for February 1, 1887. His statements are in the form of conclusions drawn from experimental work, and are as follows:

The poison of hydrophobia exists in its most concentrated form in the central nervous system (brain and spinal cord) of the animal poisoned.

Small amounts of cerebro-spinal substance, taken from a dog poisoned with hydrophobia and injected into another animal subdurally by trephining, call forth, after a latent period which varies but slightly (fourteen to twenty-one days), the same disease with absolute certainty.

From this source rabies is capable of being conveyed in a similar manner to other animals.

After subdural injection with portions of the marrow of men who died with rabies, animals become ill with the same symptoms, and after an equal time of incubation. From this fact the identity of the process in men and animals seems perfectly established.

After the subcutaneous injection of cerebro-spinal matter, the infection is less certain and the time of incubation is longer than after subdural injection of the virus.

The quantity of virus injected subcutaneously is in inverse ratio with the length of the period of incubation; the less the amount

injected, the longer the incubation period required.

Through successive subdural inoculations of cerebro-spinal substance containing the virus of rabies there resulted after a succession of generations a shortening of the time of incubation, which occurred at first very irregularly, then more regularly, and finally in decreasing length.

The fixed virus obtained from Pasteur, which was derived from the successive inoculation of forty to fifty generations of virus, and said to have seven days as a time of incubation, excelled the virus of "street rabies" in intensity, not only in that the disease appeared sooner, but also that the animals inoculated, whether by the subdural or subcutaneous method, acquired the disease *without exception*.

The virus of Pasteur appeared, when transferred through successive generations, to have no appreciably shorter time of incubation (animals were sometimes made ill on the sixth day), while the period was not constant at seven days, but was sometimes extended to ten, and even twelve days. The transference of "street rabies" virus for two or three generations resulted in an incubation period of from eight to twelve days, and a virus of equal intensity with Pasteur's laboratory virus.

A virus like that of Pasteur with an incubation period of seven days can, be obtained not only by his method but also by a series of transfers, which bring it much earlier to its potency, and this virus shows itself very constant in its effect and period of incubation.

Drying the cerebro-spinal substance at 20° C. over caustic potash greatly diminishes the virulence of the matter, and after fourteen to sixteen days of such treatment its power has entirely gone.

Animals for experiment which were inoculated with progressively diluted virus subcutaneously, were protected by this from the action of stronger virus, provided that the series of injections of progressively stronger virus did not follow each other too rapidly.

In contradiction to Pasteur's statement, animals inoculated for ten days with virus increasing in strength, but subcutaneously administered, were not proof against "street rabies;" it was only when the inoculation was subdural that immunity was sure.

Rabbits and dogs which, after subdural inoculation with "street rabies," were treated by the prophylactic inoculation given subcutaneously, were seized with rabies.

Pasteur insists that prophylactic inocula-

tion should not be delayed too long, but Von Frisch has followed his method in detail. Pasteur recommends the inoculation of an animal within twenty-four hours, repetition every two hours, and a repetition of the series of inoculations, two or three times, while the prophylactic inoculation should begin at once after infection, at least on the following day.

Experiments conducted after this plan on dogs and rabbits gave no good results; the animals developed rabies even after this energetic treatment. These experiments showed, however, a fact of value: that the rapid repetition of inoculation with material of increasing intensity did not result in protection by the weaker virus against the stronger which followed it. Among a number of rabbits and dogs upon which were performed "control experiments" to test these conclusions, and on which the intensive inoculation without previous infection was made, a very large proportion developed rabies and died with it even when the time of incubation reached thirty-four days. From these experiments the conclusion is reached that more researches upon animals must be made before reliable results can be obtained, and that we have no reasonable ground for treating human beings by prophylactic inoculation after bites while the strong probability exists that through the prophylactic inoculation, at least through Pasteur's method of intensified inoculations, the disease itself may be communicated.

TREE-PLANTING.

THE THERAPEUTIC GAZETTE is a welcome visitor to so many country firesides, and the subject of tree-planting is so closely connected with the health and prosperity of country districts, in which the medical man is looked up to as an authority upon all sorts of subjects, that we do not hesitate to occupy a few lines with calling attention of our readers to the importance of tree-culture in the United States. On the eastern and western edges of the continent nature has provided a sufficiency of forests, which are, however, in danger of rapid destruction through the hands of man. In the centre of the continent, where nature is at fault, man should reverse the process of destruction. In our opinion, neither preaching nor the hope of sanitary good, nor the love of the æsthetic, have sufficient power to move large bodies of men. The glitter of the guinea will, however, always draw, and it is therefore with great

pleasure that we read in *Science* of March 4 that the farmers of Massachusetts have learned that cultivated forests may yield a very profitable result, and that it has been demonstrated in Barnstable County, Mass., that a crop of pitch-pine can be raised from seed with as much certainty as a crop of corn, and with much less expense. In the barren, sandy, exhausted soils of Middleborough and Bridgewater white pine has been so successfully cultivated that farmers have sold logs at the rate of one hundred and fifty dollars an acre from seedlings set by themselves.

The National Agricultural Department ought to institute a series of experiments on a large scale to determine what species of trees can be most profitably cultivated in the various diverse climates of this country. Professor C. S. Sergeant, of Harvard College, states as a result of experience that he has entirely changed his opinions in regard to the comparative value of foreign and native trees. For years the imported trees were very largely planted out in New England, and at first grew rapidly and strongly, so that they were thought to be better than the native species; but all of them, as they approach maturity, cease growing, become decrepit, and fail to produce good timber. Perhaps from the list of foreign failures the willow should be excepted. Its value is not in affording timber but in producing wood adapted to peculiar purposes, such as charcoal and basket-making.

YELLOW FEVER INVESTIGATIONS.

BY the passage of the Sundry Civil Appropriation Bill, Congress has authorized the President to expend a sum not exceeding ten thousand dollars for the purpose of investigating the merits of the methods practised in Mexico and Brazil for preventing yellow fever by inoculation.

In such an inquiry everything depends upon the person selected. For the position Dr. Sternberg, of the United States army, is certainly prepared by his thorough training in bacteriology and by his having had yellow fever. Prof. John Guit  ras, of Charleston, a native of Cuba, well known by his acute articles upon tropical fevers, having had great clinical experience, speaking Spanish, and bearing about with him the immunity to yellow fever which belongs to his race, would

afford a complementary companion to Dr. Sternberg. We commend the pair most heartily to the notice of President Cleveland.

Reports on Therapeutic Progress.

MORPHINE IN DIABETES.

In the *Practitioner* for January, 1887, Dr. J. MITCHELL BRUCE publishes an account of a series of investigations which he has made as to the effects of the administration of morphine to cases of diabetes mellitus. These investigations of Dr. Bruce throw considerable light not only on the mode of action of morphine in diabetes but on the pathology of the disease itself. His method was first to ascertain the amount of sugar passed by the patient on an ordinary mixed diet; that is, allowing him to continue the same kind of food as he had been consuming when he was taken into the hospital. The patient was then placed on a strictly antidiabetic diet; having by this means reduced the sugar to something like a constant minimum, morphine was administered by the mouth, beginning with a moderate dose, and increasing the quantity by small increments as long as the glycosuria continued to yield to the drug and unpleasant symptoms were not developed, until if possible a still lower constant of sugar was reached. In this stage of the treatment hypodermic administration of the morphine was substituted for its exhibition by the mouth; thus serving to determine as to whether there was any difference in the effect of morphine on the amount of sugar passed in the urine, according as on the one hand it was allowed to pass through the liver entirely, or, on the other hand, it discharged into the general circulation, thus mainly escaping the hepatic system.

The conclusions which Dr. Bruce feels warranted in drawing from these observations he arranges under two heads.

I. *Therapeutical*.—There can be no question that in this case morphine was of value in the treatment of diabetes. Not only did the sugar disappear entirely under the use of the drug, but the patient's weight increased four and a half pounds during the first course of morphine by the mouth, and his personal condition, subjectively and objectively, was greatly improved. It is true the improvement was but temporary; but it would be equally correct to say that the benefit continued as long as the treatment was maintained. Dr. Bruce thinks that in the treat-

ment of diabetes morphine has suffered somewhat unfairly in reputation by comparison with codeine.

II. *Physiological and Pathological.*—1. In the case before us *the glycosuria was proved to be due to an increased income of sugar into the blood; not to diminished destruction of sugar in the system.* This conclusion was established by the fact that whilst the glycosuria was controlled by morphine, the drug had very much less influence on the disorder when it was thrown into the general circulation (where destruction of sugar is accomplished) than when it was introduced into the *portal* circulation.

2. In the present case *the increased income of sugar was proved not to originate in simple transportation of sugar from the intestine or portal vein to the general circulation.* When all saccharine and amylaceous materials had been removed from the diet, the patient continued to excrete as much as 1360 (later on, even 4000) grains of sugar per diem. It was clear, therefore, that glycogenesis was still active, and that the sugar was derived from the nitrogenous constituents of the food by some organ, whether the liver situated on the portal circulation, or the muscles and other viscera, situated on the general circulation.

3. *The excessive glycogenesis that was going on in this case was proved to be effected mainly or entirely in the liver, not in the muscles or any of the other viscera.* This conclusion followed from two facts: (1) that when the morphine was introduced into the liver by the portal vein, it reduced the sugar to *nil*, whilst it did not materially affect the other viscera, such as the central nervous system; and (2) that when it was introduced into the general circulation it diminished the amount of sugar excreted only to the degree that might have been anticipated from the portion that would reach the liver through the hepatic artery, whilst it markedly affected the other viscera, such as the central nervous system.

4th and lastly, these results appear to prove that in this instance, if the diabetes was of nervous origin (as it is believed to be in some cases) the seat of the disordered process was in the liver, not in the central nervous system or nerve-trunks. This conclusion again follows from the effect of morphine by the mouth as compared with its effect *sub cute*; for the subcutaneous method distinctly proved that whilst the central nervous system was profoundly depressed by morphine, there was but little effect on the glycosuria,—through this channel, probably *none*.

THE ANTISEPTIC TREATMENT OF SUMMER DIARRHŒA.

In the *New York Medical Journal* for January 29, 1887, DR. L. EMMETT HOLT publishes an elaborate paper on the antiseptic method of treatment of summer diarrhœa, from which he draws the following conclusions:

1. Summer diarrhœa is not to be regarded as a disease depending upon a single morbid agent.

2. The remote causes are many, and include heat, mode of feeding, surroundings, dentition, and many other factors.

3. The immediate cause is the putrefactive changes which take place in the stomach and bowels in food not digested, which changes are often begun outside the body.

4. These products may act as systemic poisons, or the particles may cause local irritation and inflammation of the intestine.

5. The diarrhœal discharges, *at the outset* at least, are to be looked upon as salutary.

6. The routine use of opium and astringents in these cases is not only useless, but, in the beginning particularly, they may do positive harm, since, by checking peristalsis, opium stops elimination and increases decomposition.

7. Dr. Holt does not deny nor undervalue opium in many other forms of diarrhœa than the one under discussion.

8. Evacuants are to be considered an essential part of the antiseptic treatment.

9. Experience thus far leads the author to regard naphthalin and the salts of salicylic acid as the most valuable antiseptics for the intestinal tract.

ANTIFEBRIN.

EISENHART, in the clinic of Ziemssen in Munich, has used antifebrin, and reports as follows: The number of cases observed was thirty. The doses given were from 4 to 8 grains, given in powder and solution, by rectal and anal use. In a case of erysipelas a dose of 8 grains was vomited when given by the mouth; when given by injection it was retained.

In general the drug was well borne; half of the patients had a profuse perspiration following, and an exanthem occurred in one case.

Cases of typhoid, treated with antifebrin, had an easy course. The influence of the drug was generally manifested two hours after it had been taken. After a dose of 4

grains the temperature sank six times from one-tenth to one degree, thirteen times from one to two degrees, fifteen times from two to three degrees, six times from three to four degrees, and three times more than four degrees. After a dose of 8 grains a depression of temperature of one-tenth to one degree occurred three times; from two to three degrees, seven times; from three to four degrees, twice; from three to more than four degrees, twice. In a few cases only was this effect wanting.

In comparison with antipyrin it was found that one-fourth as much antifebrin as antipyrin was required for a given effect. The conclusions of the observer were that in doses of 4 to 8 grains antifebrin was a very valuable febrifuge, reasonably certain of success. —*Deutsche Medicinal-Zeitung*, December 23, 1887.

THE DETECTION OF COCAINE IN THE ANIMAL BODY.

HELMSING, of Dorpat, has published a carefully-prepared pamphlet reporting his experiments on this subject, and his conclusions we find to be as follows:

The method employed in testing for cocaine was that of Dragendorff, and consisted essentially in acidulating the fluid containing the poison with sulphuric acid, and shaking the mixture with petroleum ether, benzine, and chloroform. The residue after each shaking was put in a watch-glass, and a drop of potassium iodide and picric acid added. The residue left after evaporating these mixtures gave no reaction for the alkaloid until it was rendered alkaline, when it was again shaken with the three volatile liquids, and evaporation again performed, when the residue gave with potassium iodide a brilliant red precipitate, and with picric acid a white precipitate.

Quantities of the alkaloid ranging from $\frac{1}{16}$ and $\frac{1}{32}$ of a grain were detected in urine; in blood the same amounts gave appreciable reactions; in food-stuffs, traces of the drug were found in the stomach after its administration.

Cocaine was found in the urine in the case of a cat to which $\frac{1}{4}$ of a grain of cocaine had been given. The same animal received $\frac{1}{2}$ of a grain, and both fæces and urine gave reactions for cocaine. A second animal which was made the subject of experiment showed the same reactions. An animal which was poisoned by $1\frac{1}{4}$ grains of the alkaloid passed urine and fæces twice, at intervals of twenty-six hours. In the excreta voided first well-

marked reaction for the poison was observed; in the second, no trace of the drug was found. In the case of another animal which was poisoned by the same dose, and voided urine in three portions, at intervals of nine and fifteen hours, the quantity of cocaine excreted steadily diminished until none could be detected. The following organs and tissues were examined in an animal poisoned by $\frac{1}{2}$ of a grain: heart and blood, lungs, spleen, liver, gall-bladder and bile, kidneys, stomach, small intestine, large intestine, brain, muscles, bladder with the urine. In the greater portion of these organs no cocaine could be found.

The dose was then increased to $4\frac{1}{2}$ grains in the case of another animal, and the potassium iodide test gave reactions for cocaine in all the organs examined. A fatal dose of $1\frac{1}{2}$ grains could be detected in but a portion of the organs after death. It is interesting to note that the largest dose given was discoverable in all the organs of the body, and the smaller dose of $1\frac{1}{2}$ grains was found only in the liver, bladder, and urine. The elimination of the poison begins in twelve minutes after taking, when it was found in the urine; the bowels share also in excreting it. The writer adds a full list of the reagents which act upon cocaine, and a description of its lethal effects.

A SPEEDY CURE OF WHOOPING-COUGH.

MOHN, a Norwegian physician, had in his own family a case of scarlatina and whooping-cough. After the violence of the scarlatinal attack had subsided, but while the whooping-cough was still present, Mohn disinfected the child's bedding with the fumes of sulphur. Just previous to the fumigation the child had a severe paroxysm of coughing, which led the father to hesitate in his employment of the sulphur. He was surprised and gratified, however, to observe that the disease was cured; and the patient's sister, who had a cough, the sequela of pertussis, was also cured. These children were not included in the fumigation intentionally, but inhaled such vapor as casually permeated their apartment.

In a subsequent severe case, the writer, after the failure of other means, had recourse again to inhalations of sulphur gas, with prompt success. He cites successful cases of five months in age, and children of varying ages have been cured in this manner. He proceeds as follows: The patients are dressed in clean linen, and taken from their bedroom to another room. In their absence bedding, fur-

niture, playthings, linen, clothing, everything which the sick-room contained is so arranged that the fumes of sulphur can penetrate to all. Six and a half drachms of sulphur per cubic metre of air-space in the room are burned, and the fumes allowed to permeate the room for five hours. At evening the child is taken back to the sick-room and put in a bed which was disinfected; it awakes the next morning cured.—*Revue Internationale*, No. 35.

GELSEMINUM ALKALOIDS.

In an elaborate paper Mr. F. A. THOMPSON describes (*Pharm. Era*, January, p. 3) two alkaloids obtained by him from gelsemium root, thus confirming so far Messrs. Ringer and Murrell's hypothesis that the root contained two alkaloids, one of them exercising a paralyzing and the other a tetanizing influence. The alkaloids were obtained by percolating the finely-powdered root mixed with freshly-slaked lime with alcohol, shaking the percolate with chloroform, and then treating the chloroform solution with water acidulated with sulphuric acid. The separation of the alkaloids is effected by the addition of hydrochloric acid, the hydrochlorate of one of them, which is crystalline, being insoluble, and that of the other, which is amorphous, being soluble in its own weight of water. The crystalline alkaloid, for which Mr. Thompson proposes to retain the name "gelsemine," gave upon analysis results corresponding with the formula $C_{24}H_{26}N_4O_{11}$, differing, therefore, considerably from that attributed by Mr. Gerrard to the alkaloid analyzed by him (*Pharm. Jour.*, 37, xiii. 641). The amorphous alkaloid has not yet been obtained sufficiently pure for analysis.—*The Pharmaceutical Journal and Transactions*, January 29, 1887.

THE SUBCUTANEOUS INJECTION OF THE YELLOW OXIDE OF MERCURY IN SYPHILIS.

SZADEK has made clinical studies with this mode of treatment in the clinic for dermatology at Kiew in the treatment of secondary syphilis. He made thirty-five injections in six patients, and selected the gluteal region, where he injected the drug deeply beneath the muscular fasciæ.

His formula was the following:

R Hydrarg. oxydat. flavi, gr. xv;
Gummi Arabici, gr. xx;
Aquæ destillatæ, ℥viiss. M.
Fiat emulso.

His conclusions from these observations were that (1) the local reaction was very little, even less than after the use of calomel; the patient generally complained of dull pain, which ceased in a few hours; the gluteal region was not tender on pressure in two or three days after injection; hemorrhage never followed these injections.

2. In no case did an abscess form, either at the point of injection or in its vicinity; generally a small amount of infiltration was observed; in one case only, on the third day after five injections, a painless node was felt in the muscle, which soon disappeared.

3. The examination of the urine showed, after each injection, the presence of mercury.—*Deutsche Medicinal-Zeitung*, January 10, 1887.

A NEW METHOD OF SEWER VENTILATION.

A new proposal has just been brought forward for the ventilation of sewers. It has the merit of originality and ingenuity. Mr. R. S. ASH has patented a system of ventilation by the force of concussions resulting from explosions automatically produced. In the man-hole of a sewer, or in the ventilating-shaft of a coal-mine, etc., he places a small cylinder where coal-gas accumulates till it reaches a little hole, and there comes in contact with a jet burning outside. An explosion results and the lid of the cylinder is blown off, but counter-weights make it fall back in its place, so that all is ready again for the next explosion. Of course the air is blown out of the man-hole, and a vacuum created and filled by the air rushing up from the sewer, but this displacement is not the principal merit of the process. A ventilating fan or revolving wheel and a furnace will equally produce a current of air; but such current generally travels down the central and main sewers, and leaves almost untouched the accumulations of foul gas in the branch sewers, in the angles, and in other inaccessible places. A shock, however, does not travel in a straight line, but spreads out in a circle. A stone thrown into a pool of water affords the readiest illustration of this fact. Let the edges of the pond be jagged and angular, the ripple will travel up every little crevice or opening in the banks. A current, on the other hand, even the current of a rapid stream, leaves quiet nooks made by the recesses of the embankment, where a boat may be safely moored without risk of its being borne away. Thus, an explosion in a

sewer will with more certainty move the air in the branch sewers and out-of-the-way passages than will a strong current down the main channel. Also it should be noted that it is precisely these branch pipes and sewers which are nearest to the inside of the dwelling, and therefore most urgently need ventilation. Consequently, if ventilation by concussion or explosion can be made to act without involving too great an inconvenience and expense, it is likely to prove as valuable a progress in practice as it is an advance in theory. —*The Lancet*, February 12, 1887.

ANTIPYRIN IN HEMICRANIA.

UNGAR, of Bonn, was led by the similarity of action of antipyrin with salicylate of sodium to try the former in hemicrania. He found that when given in the beginning of the attack or in the prodromal period the drug either wholly prevented an attack or made it very much milder. Patients who were generally not able to be about during an attack were able, after taking it, to maintain their usual avocations. When taken after the paroxysm of pain had fully established itself, it was still able to prevent a severe onset. Antipyrin is not, however, a reliable drug in all headaches. Patients were found upon whom it had no effect; it was more rarely found that the same patient was relieved on one occasion and not on another. A reason for this variation, and a means of recognizing it, the writer had not discovered. In cases which were relieved by antipyrin, for adults a dose of 15 grains, taken without repetition, was generally sufficient; rarely 23 grains were needed, and without repetition. The good results were generally manifested in an hour after taking; when this was not the case a similar dose was added, when in several cases the desired effect followed. Antipyrin was usually prescribed in capsules or wafers. —*Medicinisch-Chirurgische Rundschau*, February 1, 1887.

tion, and hemorrhagic endometritis, in which the drug was administered continuously, while in other cases of hemorrhage at the menstrual period he has administered it for ten days before and during this period. He has never used hydrastine and the other alkaloids through his want of confidence in the constancy of their strength.

His conclusions supplement the results of treatment by other writers. He finds that hydrastis checks the bleeding from uterine hemorrhage by the production, he believes, of persistent anæmia, unaccompanied by the distressing cramps or the flooding from the alternate contractions and relaxations so often produced by ergot. Its use is therefore preferable in the case of small fibroids, where their expulsion would probably be attended by hemorrhage or septicæmia. In fungous endometritis, even when curetting has failed to arrest the bleeding, he has obtained remarkable results from the use of hydrastis.

TESTS FOR THE PURITY OF COCAINE.

HARTGE gives the following as practical tests of the purity of cocaine:

1. When heated upon platinum it must disappear without residue.
2. Solutions of cocaine must be of neutral reaction.
3. Sulphuric acid, when added, should not discolor its solution.
4. When to a solution of cocaine, 1 to 200 or 1 to 500, one drop of a two per cent. solution of potass. permanganate is added, the liquid should become red but remain clear. If the permanganate is added in drops beyond this point, a red precipitate of cocaine will fall, which will become brown on heating, but will give no odor of bitter almonds.

The writer tested six samples of cocaine, finding only one pure. —*Der Pharmaceut.*, January 15, 1887.

HYOSCINE IN KIDNEY-DISEASES.

In the *Practitioner* for February, 1887, DR. NESTOR TIRARD reports the case of a man, aged 58, suffering from chronic kidney-disease, in whom obstinate sleeplessness formed one of the most rebellious symptoms. For a time this condition was relieved by moderate doses of chloral and bromide of potassium, but this combination gradually lost its effect. After a time the tincture of cannabis indica was employed, but the result was disappoint-

HYDRASTIS CANADENSIS IN UTERINE HEMORRHAGE.

DR. REYNOLD W. WILCOX reports in the *New York Medical Journal* for February 19, 1887, forty-three cases of various forms of uterine hemorrhage in which he has employed the fluid extract of hydrastis canadensis in doses of 20 drops three or four times a day in a wineglassful of water. The cases included cases of fibro-myomata, sub-involu-

ing; finally the hydriodate of hyoscine was employed in the strength of one grain to two hundred minims of distilled water, of which 2 minims were injected subcutaneously. This injection produced sleep, but constant wandering delirium, which increased with the repetition of the dose until the quantity was reduced one-half. The result was, then, that a quiet delirious condition came on almost invariably from ten to twenty minutes after the hypodermic injection and then passed on into sound sleep. Dr. Tirard notes, what seems to have been peculiar in his experience, that there was frequently dryness of the throat, and on one or two occasions the patient awoke with a feeling of nausea, which soon passed off. The pulse did not vary in volume, but always fell five beats or more after the injections. There was absolutely no interference with accommodation, no change in the size of the pupil, nor any marked change in reaction to light.

The conclusions which Dr. Tirard draws from the observations on this case are the following:

"Hydriodate of hyoscine is a drug which can be used with perfect safety in cases of kidney-disease where morphine is inadmissible. It is a drug which may give rest when other sedatives fail.

"If used in 2-minim doses subcutaneously it may give more satisfaction to the patient than to the attendants, since the unconsciousness may be accompanied by angry and combative delirium. Should this occur, it will probably be sufficient to diminish the amount employed.

"It is very rapid in its action, unconsciousness following in from ten to twenty minutes, and the after-effects are of a soothing character.

"Even when delirium is present in a violent form, it is followed by quiet sleep, and the patient, being unconscious, is much more refreshed than by a night of short snatches of sleep produced by chloral or bromide, and the result is a marked improvement in both aspect and temper. And, lastly, no irritation is produced around the site of injection."

NAPHTHALIN.

BORELIUS, of Upsala, gives the results of his clinical uses of naphthalin as follows: Following the advice of Rossbach, the drug was used in cases of chronic intestinal catarrh with good results when all other means of cure had failed. In abdominal typhus, even

when pushed to 4 scruples daily, no effects were obtained. The best results were gained in tuberculosis of the intestines. Three cases which had presented obstinate abdominal pain and severe general symptoms were relieved after taking naphthalin with powdered coffee four or five times daily in doses of 7 or 8 grains. The post-mortem examination in these cases showed the intestinal ulcers clean and in process of healing, and many of them already cicatrized. The urine was often colored darkly, but in one case only was dysuria observed, which became so severe that the drug was abandoned.—*Medicinisches-Chirurgische Rundschau*, January 1, 1887.

ABSORPTION FROM THE MUCOUS MEMBRANE OF THE URINARY BLADDER.

The question as to the occurrence of absorption through the mucous membrane of the urinary bladder has often been considered both at the bedside and in the laboratory, but the results have hitherto been sufficiently discrepant to leave room for more exact work on the subject. The latest contribution towards a solution of the problem bears the mark of exact scientific observation, and seems to us largely to settle the matter. In the current number of the *Journal of Anatomy and Physiology* there is a paper on "Absorption from the Mucous Membrane of the Urinary Bladder," by DR. HERBERT H. ASHDOWN, late senior demonstrator of physiology in the University of Edinburgh, in which a critical summary of the work already done is given, and a series of carefully-conducted experiments is reported. The observations were made on rabbits and dogs, and consisted essentially in the analysis of results obtained by the intravesical injection through the urethra of substances possessed of known physiological properties or readily estimated chemical reactions. The author divides his experiments into three groups: (1) Those in which the drugs administered have a sufficiently distinct physiological action of their own to indicate their presence when absorbed into the system. (2) Those in which the renal elimination of the drugs given can be readily demonstrated. (3) Those in which the quantitative analysis of a solution of known chemical composition can be conducted after it has remained for several hours in the bladder. The results of the triple series are strikingly similar, and appear to justify Dr. Ashdown's conclusions. These are: (1) That absorption of a very large series of chemical substances does take

place from the mucous membrane of the urinary bladder when in a perfectly healthy condition. (2) That the urinary constituents themselves—those substances eliminated by the kidney as effete products of the system—are absorbed from the bladder in varying proportions, this applying more especially to the water and urea, but also, though to a less extent, to the inorganic solids. (3) That the degree of distention of the bladder plays a most important part in increasing or diminishing the rapidity of such absorption. (4) That regular rhythmical contractions take place in the muscular wall of the bladder; that these contractions are largely influenced by the degree of distention of the bladder, being most marked with a moderate amount of distention of the viscus, and but feebly marked in slightly distended or in over-distended conditions; and that the character of these contractions is largely affected by the nature of the fluid contained in the bladder.—*The British Medical Journal*, February 12, 1887.

PYRIDIN IN ASTHMA AND OTHER DYSPNŒAS.

The clinical studies of KELEMIN, of Buda Pest, have given us the following information regarding this drug :

In both inspiratory and expiratory dyspnœa its use was constantly followed by success; subjective and objective symptoms were alike relieved. While the effects of the drug varied with the peculiarities of the patient, its use was peculiarly efficacious in pulmonary, cardiac, and renal asthma. The writer was almost led to consider it a specific in pulmonary and cardiac asthma.

The effect of the drug in the cases which showed emphysema endured from eight to twelve hours. The curative properties of pyridin are not yet established. In two cases where marked psychic disturbances followed the abuse of morphine and chloral, the patients were greatly benefited by this remedy. The interesting question arises whether pyridin can so alleviate dyspnœa that asthmatics may be freed from the necessity of using chloral and morphine; if this result be attained it will be truly valuable.—*Medicinisches Chirurgische Rundschau*, January 1, 1887.

DIGITALIN.

Whilst working out the toxicology of digitalin, M. LAFON has made the observation

(*Archives de Pharm.*, January, p. 32) that this glucoside is not acted upon by diastase, pepsin, gastric juice, pancreatic juice, bile, beer yeast, emulsin, or the putrefactive ferment. It is not, therefore, sensibly modified in the digestive canal, but it undergoes a profound alteration in the circulation, which is probably due to an oxidation process. It was also found that the detection of digitalin is not prevented by the action of alkalies, or that of sulphuric, phosphoric, or hydrochloric acids; nitric acid, on the other hand, appears to decompose it.—*The Pharmaceutical Journal and Transactions*, January 29, 1887.

COTTON-ROOT AS A UTERINE HÆMOSTATIC.

In a paper read by DR. HENRY GARRIGUES before the Medical and Surgical Society of German Physicians of New York, and published in the *New Yorker Medicinische Presse*, as reported by the *Pittsburg Medical Review*, January, 1887, Dr. Garrigues stated his experience with the cotton-root (*Gossypium herbaceum*), of which he has made very extensive trials in all forms of uterine hemorrhage during the last two years, and which, in his hands, has certainly proved remarkably successful.

He treated one hundred and thirty-nine patients afflicted with different forms of uterine diseases, in whom hemorrhage had been a very prominent symptom, with this drug, with the following results :

	Relieved.	Not relieved.
Anteflexion.....	33	2
Anteversion.....	1	...
Retroflexion.....	8	...

Sanguineous leucorrhœa after menopause.....	1	...
Menorrhagia and metrorrhagia from unknown causes.....	38	5
	125	14

If the same patient presented different affections at the same time, viz., laceration of the

cervix, cellulitis, and flexion, she was only mentioned once, and that under the diagnosis which is the most frequent cause of hemorrhage,—e.g., in the case cited, under flexion.

When there were indications for other methods of treatment, these were fulfilled, viz., the polypus was removed; in case of ectropion of the cervical mucous membrane, injections with liq. ferri sesquichlor. (3ss to one pint of water) were ordered; in hyperplastic endometritis the curette was employed; malpositions were corrected and a pessary introduced; pelvic inflammations were treated with hot douches and glycerin tampons, and syphilis by specific medication.

Though this combined treatment was employed, he feels justified in drawing the same conclusions in regard to this root as a hæmostatic as he formerly did when using in its place fluid extract of ergot, fluid extract of viscum album, tincture of cannabis indica, tincture of capsicum, and bromide of potassium. Since he commenced to use the cotton-root he has always prescribed it first, and if it failed he has had recourse to the old remedies. In cases in which he could not detect any particular cause for the hemorrhage, he used cotton-root alone. He treated many other cases in hospital and private practice in the same way, of which he has, however, kept no record.

In the beginning he prescribed the fluid extract, but found it of very little benefit if not taken in very large doses, which were not tolerated well by the patients. These cases, however, were omitted in the above table, which has reference only to those treated by the drug in the form of a decoction. He directs to boil three large teaspoonfuls in a pint of water for fifteen minutes, then to strain it, and to drink it cold in three portions,—morning, noon, and night. This decoction has a red color, something like raspberry lemonade. It has an aromatic, slightly astringent taste, and is not unpleasant to take.

This decoction has tonic properties which are of value, as preparations of iron are contra-indicated until all tendency to bleeding has ceased. Patients should take it for months. During menstruation they should discontinue it for from two to four days, according to the amount of blood lost, when it should be resumed again. Like all other remedies, it is not a specific; in some patients it fails entirely, while other remedies, especially ergot, give relief; in other cases all hæmostatics are absolutely useless. He has found it, however,

preferable to all other remedies in the majority of cases. It seems to have a most remarkable effect in neoplasms; in fibroids it very often not only relieved the hemorrhages, but also the pains. Even in cases of cancer and sarcoma of the uterus, he found it very beneficial as a hæmostatic and tonic.

DESCRIPTION OF ANTIFEBRIN.

CAHN and HEPP, its discoverers, describe it to be acetanilide or phenylacetamide, with the formula $C_6H_5NHC_2H_5O$ (*Centralblatt für die Medicinischen Wissenschaften*, January 8, 1887). It is produced by the action of heat upon aniline acetate, one molecule of water being driven off. It is a white, crystalline, odorless powder, which burns the tongue slightly; is almost insoluble in cold water, requiring one hundred and sixty parts for its solution, sparingly soluble in hot water, and very soluble in alcohol and wines. It is of neutral reaction, and is very stable against most means of chemical reduction.

It melts at $113^{\circ} C.$, and volatilizes at $292^{\circ} C.$ In large doses it produced no ill effects upon animals, and did not influence the normal temperature.

It may be conveniently administered suspended in water, as it has no bad taste, but only a slight and not unpleasant sensation of burning, and patients evince no aversion to it, even after its administration for a long time.

The discoverers report their observations upon twenty-four patients with pyrexia, and draw the following conclusions:

The doses were from 4 to 8 grains. In single doses of considerable size the best effects were produced. In comparison with antipyrin the relative strength is four to one in favor of antifebrin.

The influence of the drug began in an hour, reached generally its maximum in about four hours, and was finished in from three to ten hours. The fall of temperature which occurred after its influence was established was marked by perspiration and reddening of the skin; the rise of temperature which followed was without chills, but often with a sensation of cold. The frequency of the pulse was diminished with the decreased temperature, and arterial tension was increased. Ill after-effects were not observed. In some cases, during the reduction of temperature, thirst, diuresis, and quiet sleep occurred.

Frequently cyanosis of the face and extremities was present, which began with the fall of temperature and ceased without being followed by a chill. Antifebrin gave prompt and satisfactory results in acute joint-rheumatism.

According to an analysis of some more recent studies by the same authors published in the *British Medical Journal* for February 12, 1887, it is four times as strong as antipyrin in its effects, is very cheap, does not cause vomiting, and rarely causes any rigors, as the temperature subsequently rises again. Moreover, it causes no cerebral disturbance, and the appetite even improves under its use. In a few cases, some degree of cyanosis of the face and limbs was observed; this, however, always disappeared (without any symptoms of shivering as it faded off), and the authors paid very little attention to it. Indeed, they complain that certain remarks in some chemical advertisements have been exaggerated in this particular, in order to favor the sale of antipyrin, and distinctly state that the above appearance was not more frequently observed than after other antifebrile agents, far less than after kairin. To call it "aniline-poisoning," as has been done, is quite unjust.

The drug was used in twenty-four cases of fever, and always lowered the temperature: 15 grains given in the morning is the favorite daily dose with Drs. Cahn and Hepp. The temperature began to fall in about an hour, and continued to fall for about three hours longer; it then gradually rose again; as the temperature fell, the skin reddened, and there was perspiration; the pulse became less frequent, and the arterial tension was increased. In some cases, during the period of intermission, there was much thirst, followed by increased urination and gentle sleep.

A further series of cases, sixty in number, included twenty-nine of typhoid fever, six of erysipelas, two of croupous pneumonia, four of acute rheumatism, six of phthisis, two of pleurisy, two of pyæmia, and two of septicæmia. Liebermeister has taught us that quinine is more energetic in its effects if given coincidentally with the natural daily remission in fevers, and this is also the case with antifebrin. A dose given early in the day has a far more potent effect than if given in the evening. A good dose at one time is far better than small doses frequently repeated, and in high fever the latter treatment is useless at first. But, if the temperature be brought to the normal by a good daily dose (15 grains) for two or three days consecutively, it will

be found that small doses of 2 or 3 grains daily will often suffice to keep it low afterwards.

As to the limit permissible, the authors themselves repeatedly took 1 or 2 grammes a day without the least effect; and one young man, who was suffering from diarrhœa, took 3 grammes (46 grains) daily for a week without the least discomfort. Indeed, Fürbringer and Reise raised the dose boldly to over 90 grains daily without harm,—a dose certainly equivalent to 5 drachms of antipyrin. Thus there is no cause for disquietude with the moderate doses recommended, but it is always advisable to study the individual susceptibility.

But one of the chief advantages of antifebrin over antipyrin is the freedom from vomiting after it, and patients who usually had retching, or even vomiting attacks, after antipyrin, took antifebrin without any discomfort. No irritation of the urinary passages was observed. In some cases of albuminuria, the albumen disappeared during the use of the drug; in others, not till the patient was free from fever. Again, shivering was rarely seen after antifebrin, whereas it is a common result after antipyrin.

The patients feel much better after antifebrin, and the mind is cleared to a remarkable extent. This is best noticed in typhoid cases.

Another advantage of antifebrin is the rise of arterial tension, together with lessened frequency of the pulse. Even when directly injected into the veins of animals, antifebrin never causes lowering of the arterial tension. This was established by experiments in Professor Schmiedeberg's laboratory. At the same time the increased diuresis caused by antifebrin is distinct evidence of its favorable effect upon the circulation.

No specific action of this drug is claimed as against any disease in particular; the chief experiences of Cahn and Hepp related to typhoid.

From all this it appears that, as said above, antifebrin is evidently a powerful antifebrile agent worthy of further trial. It is no doubt unfortunately true that the action of these aniline derivatives is of a more or less evanescent character, but this may be compensated to a great extent by giving them in appropriate repeated doses. It may be added that Lépine (*Semaine Médicale*, 1886, p. 473) calls this agent a "nervine," and finds that it relieves the peculiar pains common to "tabid" subjects.

ALKALOIDS OF *BERBERIS VULGARIS*.

A contribution towards clearing up the confusion concerning the berberis alkaloids has been made by DR. O. HESSE (*Berichte*, xix. 3190). Dr. Hesse states that in the root of the *Berberis vulgaris* berbine is accompanied by at least four other alkaloids. Upon treating a mother-liquor of berbine hydrochlorate with soda, a dark-colored precipitate is thrown down, from which ether removes not only oxyacanthine, as stated by Wecker, but at least two other alkaloids, whilst another brown-colored amorphous base remains undissolved. The oxyacanthine may be obtained as sulphate by dissolving the mixture taken up by ether in acetic acid and adding sodium sulphate to the solution. By treating the mother-liquor with sodium nitrate another alkaloid can be separated that has been named "berbamine," whilst the third alkaloid is thrown down by excess of ammonia. Oxyacanthine presents the peculiarity of having two widely separated melting-points; when precipitated by ammonia from an aqueous solution of the hydrochlorate as sulphate it forms a white, flocculent mass, which loses water at 100° C. and melts between 138° and 150° C., but when crystallized from ether it forms anhydrous needles that melt first between 208° and 214° C. It forms well-crystallized salts with acids, and its composition is represented by the formula $C_{18}H_{15}NO_3$. In the presence of caustic alkali oxyacanthine readily undergoes modification to β -oxyacanthine, which is no longer soluble in ether, and which probably differs in the fixation of the elements of a molecule of water, but on treatment with hydrochloric acid the water appears to be separated again, normal hydrochlorate of oxyacanthine being formed. In this respect the alkaloid presents some resemblance to narcotine. Berbamine is also represented by the formula $C_{18}H_{15}NO_3$.—*The Pharmaceutical Journal and Transactions*, January 29, 1887.

RESEARCHES UPON THE DIGESTION OF ALCOHOL.

GLUZINSKI, of Krakau, reports the following results from his experiments upon the digestion of alcohol:

It disappears rapidly from the stomach.

Aldehyd cannot be detected, and most probably alcohol is absorbed as such into the circulation.

The digestion is divided, when alcohol is taken, into two phases,—that occurring in the presence of alcohol; that which takes place

after its absorption. The first period is marked by a somewhat retarded digestion of albuminates; the second exhibits the secretion of a large amount of fluid containing an abundance of hydrochloric acid. The mechanical power of the stomach is moderately increased.

The secretion of gastric juice continues after active digestion has ceased longer with than without the use of alcohol.

Under the influence of alcohol large quantities of fluid are collected in the stomach, which become tinged with bile. Comparison of digestion when alcohol is used as an aid to the digestion of considerable quantities of food and when it is not used, shows that small doses improve digestion. The explanation of this fact lies in the large quantity of hydrochloric acid which is secreted after the absorption of the alcohol, which results in the digestion of large amounts of albumen which remain. The retardation of the secretion of the first period endures much too short a time, after the use of small quantities of alcohol, to be of importance.

The diminution of the mechanical activity of the stomach is much too small to be of moment. When, however, large quantities are taken, the result is different; for example, one hundred cubic centimetres of twenty-five per cent. alcohol is absorbed from the stomach in fifteen minutes; but with much larger amounts the movements of the stomach are hindered, food remains longer in the stomach, and the rapidity of digestion is much retarded. The administration of alcohol before food results in favor of digestion, from the fact that the acid resulting from the effect of the stimulus is an aid in digestion.

In cases alike of lessened and increased formation of acid the use of strongly alcoholic drinks is prejudicial, from the fact that diminished secretion will be still further lessened and increased formation of acid still more increased. When, however, the condition of the patient demands a nervous excitant, alcohol should be given before meals.—*Deutsche Med. Zeit.*, Jan. 3, 1887.

DIAGNOSIS OF GASTRIC DISEASE.

ZWEIFEL, of Zürich, has reached the following conclusions from clinical studies:

Delay in digestion is a symptom of gastric disease, most pronounced in dilatation and cancer, least in chronic catarrh, slightly developed in ulcer of the stomach.

In gastric ulcer, with extensive and recent destruction of mucous membrane, the period of absorption is much lengthened; in cancer of the cardiac portion it is much shorter than when the cancer is at the pylorus.

When absorption from a fasting stomach lasts more than twenty minutes, dilatation or cancer of the pylorus, or possibly both, are present if the presence of extensive and recent ulceration is excluded. When by distending the stomach, or examination with a sound, it is proven that dilatation is not present, pyloric cancer is probable.

A differential diagnosis between carcinoma and simple ulcer can hardly be made from the single symptom of delayed absorption. When dilatation exists, delayed absorption will not show the presence of cancer, but the presence of a tumor; general cachexia and the absence of free hydrochloric acid are needed to complete a diagnosis.

A differential diagnosis between gastric catarrh and ulcer is not possible from the condition of absorption alone.

In diseased stomachs the difference in the rate of absorption between filled and empty stomachs, and in the same individual on different days, is less than in healthy subjects.

Gastric ulcer and dilatation can be so successfully treated that a normal power of absorption is established.—*Deutsche Med. Zeit.*, Jan. 3, 1887.

THE ACIDS OF HEALTHY AND DISEASED STOMACHS.

CAHN and MERING have made the following observations:

It is possible to estimate quantitatively the amounts of lactic and hydrochloric acids in the same stomach.

In normal cases we find a half-hour after the ingestion of food a certain amount of hydrochloric acid.

With purely meat diet hydrochloric acid only is present.

The stomachs of healthy and diseased persons contain, when mixed diet is taken, in addition to hydrochloric acid, considerable quantities of fermentation acids and mixed acids, and these quantities increase the longer the food remains in the stomach.

In fever and severe anæmia hydrochloric acid may be absent.

In amyloid cachexia hydrochloric acid is generally present.

In cancer of the pylorus the presence of

hydrochloric acid is the rule, its absence the exception; it is present, not in traces, but in considerable amounts.

Methyl-anilin-violet is colored blue by the hydrochloric acid of the stomach, and is a test for its presence.—*Deutsche Med. Zeitung*, Jan. 3, 1887.

INTRA-PULMONARY INJECTIONS.

DR. ARTHUR RANSOME publishes in the *Medical Chronicle* for January, 1887, the account of one case of gangrene of the lungs and four phthisical cases which were treated by intra-pulmonary injections. The one case in which the treatment was thoroughly carried out was that of gangrene of the lungs occurring in a woman, aged 33, in whom gangrene followed an attack of acute pneumonia. The diagnosis was readily made that the case was one of gangrene of the right base of the lung, with a cavity upon the left side due to bronchiectasis. The patient was ordered iron and quinine, and inhalations of carbolic acid through hot water, with eucalyptus oil on a respirator inhaler. These means somewhat diminished the fetid odor of the breath and the sputum, and two days later 10 minims of an ethereal solution of iodoform—1 grain in 5 minims—were injected into the cavity on the right side, and a similar injection was made daily into this cavity, except upon two days, when it was injected into the left cavity, where it caused much more pain than upon the right. After two days of this treatment it was noticed that the sputum had lost its prune-juice color, and was less offensive, and the patient felt better, but the cough and amount of muco-purulent expectoration remained excessive. Subsequently an emulsion of iodoform in olive oil was employed as an injection, with much less pain to the patient, and this treatment was continued, with intervals of a few days, for several weeks, during which time she gained about ten pounds in weight and improved greatly in general health; even the bronchiectasis disappeared; and, though the cavity in the right lung was still perceptible, the patient, at the date reported, had no cough, no expectoration, and appeared to be in good health.

The injections were made by inserting a long needle between the ribs, near the upper margins of the lower one. Care was taken to ascertain if the end of the needle had reached the cavity, or, at any rate, an air-space, by withdrawing the piston, and, unless air bub-

bled through the fluid, the needle was moved slightly, until this sign of having penetrated into the air-channels was observed.

In the treatment of the cases of phthisis some good effect was temporarily produced in two cases; but, on the whole, the results were not encouraging. Apart from the danger of accident, such as hemorrhage or pneumothorax, the procedure is somewhat alarming and disagreeable to the patient. The ethereal solution was very painful, and the olive-oil emulsion was so viscid that a larger needle had to be used than was absolutely safe.

The solution of iodoform in oil of eucalyptus was the most satisfactory of all the mixtures that were tried.

THE USE OF SPLEEN-PULP IN ANÆMIA.

MARAGLIANO has reported the results of his experiments with spleen-pulp in cases of impoverished blood and the conditions depending upon it. The pulp was given with an emulsion of bitter almonds in accordance with the following formula:

R Emuls. amygd. amar., ℥x;
Pulpæ splenicæ, ℥iv;
Spt. vini gallici (cognac), ℥ii.

This amount was given in twenty-four hours with meals. The diet consisted of soup with rice, or bread, at eight o'clock in the morning; a second soup, with four ounces of meat and bread, with a glass of wine, at noon; and a third soup at six in the evening. Five cases of chlorosis were treated in this manner, with the result, in from eight to twenty-five days, as follows: increase of general strength, increase of red blood-corpuscles; rapidly restored functional activity of the nervous, digestive, circulatory, and urinary mechanisms; increase of arterial tension and body-weight. The number of cases is manifestly too small for accurate results, but sufficiently large to awaken interest in the mode of treatment.—*Deutsche Medicinal-Zeitung*, January 3, 1887.

AN EXPERIMENTAL RESEARCH UPON RABIES.

At a meeting of the Philadelphia Academy of Surgery, held February 7, 1887, DR. HAROLD C. ERNST, of Boston, read a paper on the above subject (*Medical Times*, February 19, 1887).

His experiments were performed with three objects in view: first, to determine whether or not there was such a thing as a virus of rabies; secondly, if there is such a virus, does drying at an even temperature modify its strength? thirdly, does the inoculation of such modified virus afford immunity against the inoculation of a stronger virus?

The different series of experiments relating to these various points were then given in detail. The animals used in most of the experiments were rabbits, although guinea-pigs and dogs were also employed.

The following conclusions were reached:

1. That there exists in the cords and brains of animals inoculated in Pasteur's laboratory a *specific virus* capable of the production of similar symptoms through a long series of animals.

2. That these symptoms are produced with absolute certainty when the method of inoculation is by trephining the skull and injection under the dura mater; with less certainty when the inoculation is by subcutaneous injection.

3. That the strength of this virus is lessened when the cords containing it are removed from the animals and placed in a dry atmosphere at an even temperature.

4. That the symptoms produced by the inoculation of this virus only appear at a certain period of incubation, distinctly shorter when the inoculation has been done by trephining than when done by subcutaneous injection.

5. That injections of the virus modified in strength by drying, and in the manner prescribed by Pasteur, exert a very marked protective influence against an inoculation with virus of full strength.

6. That a very moderate degree of heat destroys the power of the virus entirely, whilst prolonged freezing does not injure it.

AN UNUSUAL CASE OF ACUTE INTOXICATION FROM MORPHINE.

SCHEIBER, in the November meeting of the Society of Physicians of Budapest, reported the following interesting case:

A neurotic woman, aged 54, suffering from a severe neuralgia, was given in three days' time $\frac{1}{10}$ of a grain of morphine hypodermically. After taking the last injection she passed into a deep sleep, which persisted forty-eight hours, during which she exhibited the following symptoms of severe morphine intoxication: convulsive movements and cy-

anosis in the face, dry tongue, loud tracheal râles, dyspnoea, perspiration, incontinence of urine and of faeces, subnormal temperature. The patient recovered in the main in three days, but exhibited for six weeks the following symptoms: aphasia, agraphia, alexia; a small bed-sore upon the buttock, and a small dry crust upon the right heel; entire amnesia; disturbances of mind, which showed themselves in irritability, childish movements, and deceptions of the senses.

The neuralgia of the right lower extremity disappeared, as did the most prominent nervous disturbances after galvanization of eight days. Scheiber attributes the symptoms in the case to acute morphine intoxication followed by profound disturbance of nutrition, and well-marked cerebral hyperaemia and capillary apoplexy.—*Centralblatt für Nervenerkrankunde*, January, 1887, No. 1.

RECTAL INJECTION OF GASES IN DISEASES OF THE LUNGS.

The Paris correspondent of the *British Medical Journal*, February 12, 1887, writes that at a recent meeting of the Biological Society, M. MOREL commented on M. Peyrou's experiments on the effects of the rectal injection of sulphuretted hydrogen in dogs, and compared the doses with those employed in the treatment of tuberculosis. One hundred and fifty cubic centimetres of a saturated solution of sulphuretted hydrogen were injected in two doses at intervals of three minutes. Symptoms of poisoning began to be manifested within two minutes, and death took place in ten minutes. Another dog died quickly after two injections of the same strength, given at intervals of twelve minutes, while two others, in whom only very small quantities of the gas, or large quantities very much diluted, had been injected, experienced only slight inconvenience, and rapidly recovered. M. Peyrou concludes that sulphuretted hydrogen is harmless only when injected in small doses. With regard to these experiments, M. Morel observed that the quantities injected were enormous, being ten or fifteen times as great as those employed in man; and, supposing the dog to be four times lighter than man, the dose injected in the dog was really forty or fifty times as great as that employed in man. M. Morel then described in detail the mode of proceeding in the treatment of tuberculosis. The patient should be placed on his back in a position to

allow free expansion of the intestines, and the operator must carefully note any resistance to the entry of the gas, so as to allow absorption to take place during the operation. The breathing should be watched, especially when the pulmonary lesions are extensive, as any deficiency in respiration will make the elimination of the gas correspondingly difficult. Moreover, the substance used in the above experiments on the dog is not the same as that employed in pulmonary affections. In the latter case, the gas which is injected is a mixture of carbonic acid and sulphuretted hydrogen, and possesses properties very different from those of sulphuretted hydrogen alone. When intestinal irritation takes place, it is because the gases are not properly mixed. M. Peyrou injected into the dog twenty-five, thirty-five, ninety, and even one hundred cubic centimetres of sulphuretted hydrogen dissolved in a considerable quantity of water. In man, the quantity injected is not more than twenty-five cubic centimetres. M. Morel then described an apparatus for making these injections, the chief objects aimed at in its construction being to prevent any atmospheric air from mingling with the sulphuretted hydrogen and carbonic acid, to moisten the gaseous mixture, and to prevent too great distention of the intestine.

LEAD-POISONING FROM CHOCOLATE WRAPPED IN TIN-FOIL.

JOHANSON, of St. Petersburg, writes of the frequent use of tin-foil as a wrapper for chocolate, cheese, tea, tobacco, and other articles, and refers to cases already in print in which poisoning from the lead contained had occurred. The need for sanitary inspection and regulation in the sale of such articles is evident.

A certain per cent. of lead in tin-foil is recognized as permissible, according to Hegar 6.6 per cent., while others give fourteen per cent., while an overweight of tin will cause lead to be absorbed by the material which is enclosed by the foil. In these cases paper is generally interposed between the foil and its contents.

Johanson took three samples of chocolate from St. Petersburg manufactories, two of which were carefully separated from the foil by paper, and examined the chocolate by boiling one gramme with diluted nitric acid, and treating the filtrate with sulphuric acid and alcohol, when the lead present was pre-

cipitated. The two packages of chocolate wrapped in paper as well as in foil gave an amount of lead sulphate equal to 94.1 per cent. and 94.6 per cent. of the metallic lead; the chocolate wrapped in tin-foil only gave .7 per cent. of lead. As all three packages came from the same factory, it was evident that the dealer had purposely separated the cheaper foil from the chocolate by paper.

The use of paper is not a sure protection, however, for chocolate is seldom free from water, and when kept for some time the water may penetrate the paper, and oxidation, the formation of salts, solution and the deposition of lead in the material enclosed follow.—*Pharmaceutische Zeitschrift für Russland*, Jan. 11, 1887.

TRANSPLANTATION OF TENDON FROM ANIMAL TO MAN.

The Paris correspondent of the *British Medical Journal*, February 12, 1887, refers to a note by M. PEYROT on the transplantation of tendon from an animal to man. The patient, a boy, aged 14, entered the Hôtel Dieu in October, 1885. Six months previous to that date, he had received a wound on the palmar aspect of the first phalanx of the left middle finger, near the groove between the first and second phalanx. The flexor tendons were completely divided, and the finger was forcibly drawn back by the extensors. Simple suture of the two ends was out of the question, on account of the great length of time that had elapsed since the infliction of the injury. On October 30 an incision was made over the first phalanx in its palmar aspect, extending into the palm of the hand for a distance of about four centimetres. The ends of the tendon having been found with some difficulty, a piece of flexor-tendon thirty-three millimetres in length was taken from the hind paw of a young dog, and united to the vitalized ends of the divided tendon by three stitches of catgut. The incision itself was brought together by two rows of stitches; a deep one, near the transplanted tendon, in order to form a sheath, and a superficial one, in the skin. The operation was done with the most minute antiseptic precautions. When the first dressing was removed, ten days after the operation, it was found that there had been no suppuration; but unfortunately union had not taken place. There was, however, no sloughing, and the wound healed well. When the patient left the hospital on January 4, 1886, he had regained the use of all the fingers of the injured hand,

though the movements were still feeble. In a similar case in a child aged 2½ years, the transplanted tendon (the tendo Achillis of a cat) was completely eliminated three weeks after the operation. M. Peyrot considers that, as a general rule, transplantation should be had recourse to only in cases of real loss of substance, or when the length of time which has elapsed since the injury has produced a definitive separation of the two ends of the tendon.

THE THERAPEUTIC VALUE OF TINCTURE OF CANNABIS INDICA IN THE TREATMENT OF SUBACUTE AND CHRONIC DYSENTERY.

In the *Indian Medical Gazette* for December, 1886, MR. S. J. RENNIE reports four cases of dysentery, the first three being subacute and chronic, and the last of the acute form, in which cure resulted from the administration of tincture of cannabis indica, even after ipecac with opium, Dover's powder, nitrate of silver injections, and various other modes of treatment had failed.

Mr. Rennie first tried the officinal tincture in doses of 20 minims three times daily, but he has since found that this dose sometimes produced slight toxic symptoms, and he has consequently reduced the quantity to 15 minims, and prescribes it according to the following formula:

R Tinct. cannabis indicæ, ℥xv;
Bismuth. subcarb., gr. v;
Mucilag. acac., ℥ss.
Misce, et adde
Tinct. zingiberis, ℥xx;
Tinct. carda. co., ℥xx;
Spt. chloroform., ℥xx;
Aqua cinnamom., ad ʒi ter die sum.

Even in these doses it is necessary sometimes to order it to be taken after meals, as it occasionally produces vertigo. It is pleasant to take, and there is no subsequent nausea. The administration requires to be kept up for several days after all symptoms have ceased.

PERSISTENT VOMITING AS A CAUSE OF EAR-TROUBLES.

Vomiting is not usually included in the list of causes which occasion catarrh of the middle ear. It is well known that aural affections frequently complicate general wasting diseases, especially in their final stages. The pharyngeal muscles waste along with the body, and the sufferer's last days are aggra-

vated by distressing tinnitus and vocal reverberation. Whenever any movement occurs in the throat, nose, or mouth, the sound is conveyed to the tympanum up the unduly patent Eustachian tube, causing an unnatural ringing and roaring noise in the ear. Added to this cause, MR. CHARLES ATKIN (*British Medical Journal*, February 12, 1887) suggests that while undue patency of the Eustachian tube will in many cases account for the symptoms complained of, the impaction of minute particles of regurgitated food or mucus in the tubes during the act of vomiting may also serve to produce aural complications. In the simple act of vomiting the contents of the stomach are not unfrequently ejected from the nostrils, and the tubal orifices may easily become plugged. Should the act be repeated constantly, as often happens in all renal and cerebral affections, the plug may be driven still farther up, until it becomes lodged at the narrowest part, at the junction of the cartilaginous portions with the bony part of the tube.

Mr. Atkin reports two cases in which such a complication occurred. The right ear, and then the left, became successively affected through the plugging of the tubes.

SURGICAL TREATMENT OF HYDATIDS OF THE LIVER.

At a recent meeting of the Royal Medical and Chirurgical Society MR. RICHARD BARWELL read a paper on widely incising, by a two-stage method, hydatids of the liver (*Lancet*, January 29, 1887). Hydatids of the liver may be treated surgically by (1) puncture with a small trocar, (2) evacuation with a large persistent opening, and (3) electrolysis. This last has not commended itself to the judgment of the profession. The author recommends that the first method should always be primarily resorted to, chiefly because it sometimes is curative,—viz., in cases of single barren cyst; but in a large proportion of cases there are numerous daughter or secondary cysts, and then the tumors frequently recur. Under such circumstances the most efficacious treatment is by keeping a large opening patent for some time. The object of the paper was to point out the safest way of making such an opening. After discussing certain other methods, it was shown that incising the abdominal parietes first, then stitching to them the cyst or its surroundings, and finally cutting into the tumor after a few days,

was regarded as a very safe and efficacious procedure. The author recommended certain precautions to be taken when the cyst-wall appeared so thin that a needle-puncture might cause effusion of hydatid fluid into the peritoneum. Some modifications introduced with a view to meet special circumstances were discussed. The case of a young woman who had a hydatid of the liver which had been punctured eight times, and on whom the author performed the above-mentioned operation, was related. After a time eighteen hydatids and the wall of a large mother-cyst were passed from the wound. There was an absence of peritoneal symptoms, and the patient made an easy recovery.

MR. W. HAWARD considered that the character of the contents of the hydatid cysts should determine the nature of the operation. Doubtless a free opening would be required if the contents were thick and compounded of daughter-cysts. He criticised Mr. Barwell's method, and thought that the potassa fusa caustic was to be selected, rather than the one which Mr. Barwell advised. His remarks were illustrated by cases. In one instance a second cyst was found bulging into the first, which had been emptied. The second one was also opened through the first, but still the patient did not recover, and finally died with lardaceous disease. Hydatids were found in the omentum and spleen, and a suppurating cyst in the back of the liver, which was doubtless the cause of the continued illness and lardaceous disease. Altogether the method of gradual perforation of the abdominal wall, so as to secure proper peritoneal adhesions, was to be preferred to other methods.

MR. HOWARD MARSH had successfully practised the operation recommended by Mr. Barwell in one case recently. The sutures had to be passed into the substance of the liver because the hepatic peritoneum was so thin. The suppurating hydatid cyst was incised four days afterwards. In a case of suppurating hydatid cysts of the liver in a little child, an abdominal section was made without attempting to secure adhesion between the liver and abdominal wall. The result was satisfactory, and the case not complicated by the extravasation of the contents of the cysts into the peritoneal cavity.

MR. HARRISON CRIPPS considered that the free incision enabled the surgeon to deal with multiple cysts, which, in his experience, were frequent complications of hydatids of the liver. A case illustrating the advantage of a

free incision was mentioned. In this instance special precautions with a view to obtaining adhesions were not used. A second cyst was completely emptied through the wall of the first cyst, which had also been completely evacuated. The results were perfectly satisfactory.

SIR DYCE DUCKWORTH had seen good results after all the methods of treatment for hepatic hydatids. He was doubtful of the excellency of the advice that all the contents of the cyst should be evacuated at the surgical operation. It was still a point for the surgeons to decide whether the cysts should be completely cleared out, and whether anti-septic injections should be practised.

MR. WALSHAM remarked that surgical treatment of hydatid cysts was not always of a harmless nature. A few cases of sudden death, even from aspiration, had been recorded. Perhaps this was due sometimes to hydatid fluid escaping into the venous circulation. He could not but think that an incision four inches long would be attended with some danger. In several cases of the kind he had made the incision from an inch to an inch and a half in length, and found this size ample for all purposes. There was but little fear of pus or hydatid fluid escaping into the peritoneal cavity, and he thought that excellent results could be obtained without the surgeon first endeavoring to secure adhesions of the cyst to the abdominal wall. After evacuation of the contents the cysts should be well syringed with carbolic acid solution, and then powdered by iodoform. In his own practice the wounds healed under this treatment with the best possible results.

DR. ANGEL MONEY said that a continental surgeon was operating by abdominal section on a case of hydatid of the liver when the patient suddenly fainted and died. A daughter-cyst must have escaped from the liver and entered into the hepatic vein, for one was found free in the right auricle of the heart.

MR. A. PEARCE GOULD thought that aspiration should be tried first in all cases. It was still an open question as to what was the best means to be adopted even in aspiration. Should the surgeon remove all the hydatid fluid obtainable, or only a small quantity? Perhaps the latter method was the safer. In one case that had been under the care of Dr. C. Y. Biss, in a woman aged 40, Mr. Gould made an incision through the right linea semilunaris, when peritoneal adhesions were found, and four quarts of pus and hydatid cysts evacuated. The patient began retching, and the

omentum protruded at the lower part of the wound. In the omentum abortive hydatid cysts were seen, but the omentum was easily returned and the sinus eventually closed. In a second case there was a very large hepatic tumor, from which reddish serous fluid, without hooklets, was drawn off. After incision two pints of fluid flowed out, and a large quantity of solid material was discovered. Some days later much of this material was scraped away, and some bleeding resulted. The case had now almost completely recovered. He was strongly in favor of the knife as against caustics. He did not think it was necessary to stitch the wall of the cyst to the abdominal wall before opening the tumor.

MR. HENRY MORRIS supposed that the chief point for discussion in the paper was the necessity or not of a double operation. In a work of Dr. W. Thompson, published in 1841, on diseases of the liver and biliary passages, four methods of treatment were fairly stated. Some quotations were made by Mr. Morris from an article published in the *Madras Quarterly Medical Journal* for 1839 by an Indian surgeon, in which the opinion was expressed that there was not much danger of effusion into the peritoneal cavity in opening abscesses of the liver. The plan of attaching the cyst to the abdominal wall was perhaps associated with that of gastrostomy and colotomy, but the procedures in the three cases were altogether different; for in the two latter operations a mobile and contracting organ had to be dealt with. In hydatids of the liver it was necessary to obtain a sufficiently large opening to allow of the escape of bulky contents. It was not difficult to secure coaptation of the cyst to the abdominal wall, and thus to prevent the escape of fluid into the peritoneum. Manipulations were also possible by which this coaptation could be secured at the time of operation. He thought that there was no necessity for a division of the operation into two stages. He could not think the procedure of Mr. Harrison Cripps—of removing the entire mother-sac—an advisable one. Once, when tempted to perform this, he had in his recollection the case recorded by Dr. Bright, in which the stripping of the parent membrane from the adventitious coat was followed by hemorrhage that nothing succeeded in stopping. Once also a boy was run over and died. It was found at the necropsy that a hydatid cyst of the liver had become detached from its adventitious capsule, with consequent fatal extravasation of blood between the true and

the false sac of the hydatid. The surgeon should, in his opinion, empty as much of the fluid and daughter-cysts as would come away without using force, but he should not attempt to remove the parent sac at the time of operation. He had never resorted to irrigation, but aseptic drainage-tubes should be used. The indiscriminate use of iodoform in the cyst might be followed by disagreeable delirium, and perhaps even death.

MR. BARWELL said that he could supply the sequel to the case narrated in the paper. A small but long sinus persisted for some time, but had recently completely healed. He had a dread of filling a large cavity with iodoform; symptoms of blood-poisoning had been known to occur after such free dressings with this powerful antiseptic.

COCAINE COTTON.

MR. K. ELLER describes in the *Druggists Circular* for December, 1886, a very easy, neat, and successful way whereby to obtain the effect of cocaine by combining it with absorbent cotton. As thus prepared, it may be applied in a variety of ways to assuage pain and bring relief to those suffering. It requires the suggestion merely in order to insure its ready preparation by an ordinarily skilful pharmacist; for instance, a given weight of absorbent cotton, a certain quantity of solution of cocaine of definite strength, and the requisite skill, and a cocaine cotton of exact cocaine value will be the result. A three per cent. solution of cocaine is a good average strength to work with, and on this basis the following formulæ are suggested, unless an exception be noted:

COCAINE COTTON.

Solution cocaine, 3 per cent., \mathfrak{z} i;
Absorbent cotton, \mathfrak{z} i.

Thoroughly saturate the cotton, carefully dry same in a current of warm air, and card the cotton to restore it to its former appearance.

COCAINE COTTON WITH MORPHINE.

(For toothache.)

Solution cocaine, 3 per cent., \mathfrak{z} i;
Sulphate of morphine, gr. xii;
Absorbent cotton, \mathfrak{z} i.

Dissolve the morphine in the solution of cocaine, and proceed as above.

To be used by introducing a small piece of the cotton into the cavity of the tooth. It can also be used for earache by moistening a suitable piece, with a few drops of water, lauda-

num, or alcohol, and carefully placing it in the ear-passageway.

BORATED COCAINE COTTON.

(For burns and scalds.)

Cocaine solution, 2 per cent., \mathfrak{z} i;
Boracic acid, gr. xxx;
Glycerin, \mathfrak{z} i;
Carbolic acid, gr. xx;
Absorbent cotton, \mathfrak{z} i.

Dissolve the boracic acid in the glycerin and cocaine solution, add the carbolic acid, and proceed as in making plain cocaine cotton.

Very useful in the treatment of burned and scalded surfaces, and also in troublesome chafing, where pain and persistent inflammation are attendants.

This list is capable of very large extension. Only this short suggestion is needed to enable the pharmacist to carry his experiments to the limit of wish or convenience.

TREATMENT OF HÆMATOMA OF THE EAR.

DR. A. LEBRUN, in a clinical lecture published in the new Brussels journal, *La Clinique*, says that after having tried various plans for the treatment of hæmatomas of the ear, including free opening as well as Follin's method of making a number of punctures, and having found them all very unsatisfactory, he has latterly injected iodoformed ether with complete success. For this two needles are inserted into the tumor at opposite points; through the larger one, No. 3 of Dieulafoy's aspirator, the contents are drawn off, the puncture being closed by means of iodoformed collodion. Then through the remaining needle, which is that of an ordinary hypodermic syringe, from 15 to 60 minims of a solution of iodoform in ether, of a strength varying from two to ten per cent., is introduced into the cavity of the tumor. This injection causes some pain, which, however, soon passes off. No dressing is required, and a complete cure results. In one case M. Lebrun twice injected a saturated solution of iodoform in ether without evacuating the contents of the tumor. This occasioned severe and prolonged pain, an eschar of the size of a half-franc piece formed, and although this healed, the process required more than three weeks. The comparatively unsatisfactory result in this case is considered by M. Lebrun to have been due to the escape of a large part of the first injection, and to overdistention of the tumor.—*Lancet*, February 19, 1887.

NOTES ON PYRETHRIN.

The root of the *Anacyclus pyrethrum*, or pellitory of Spain, has long been used in medicine for its well-known properties as a sialagogue and local irritant. Its fusiform root, that breaks with a resinous fracture, with its radiated structure and black spots, cannot easily be mistaken.

In earlier times it was officinal in the majority of the pharmacopœias of Europe, in which it formed an active ingredient in numerous stimulating powders, tinctures, and gargles.

According to Mr. C. J. S. THOMPSON (*The Pharmaceutical Journal and Transactions*, January 15, 1887) the root owes its irritating properties to its active principle pyrethrin, or pyrethric acid, a very acrid resinous substance, which resides mostly in the cortical portion. A good sample of pellitory will yield about five per cent. of pyrethrin. On analysis the root is found to contain, besides pyrethrin, an acrid resin, volatile oil, yellow coloring-matter, tannin, gum, and inulin. Pyrethrin is a soft, dark brown resinous substance, having an unpleasant odor, and extremely hot and pungent to the taste. A very minute quantity placed on the tongue causes a strong burning sensation, which shortly increases, and remains for a considerable time, inducing a copious flow of saliva. A strong solution painted on the skin causes a sharp prickling sensation, and reddens the part where it has been applied. If the part is kept covered, a blister will be produced. Pyrethrin may be obtained by evaporating a washed ethereal extract, or the following more satisfactory method may be employed: Reduce the root to a coarse powder, and exhaust it by means of percolation with alcohol. Acidulate the percolated powder with acetic acid, and boil with more alcohol, and filter; mix the liquids and evaporate.

It is soluble in ether and alcohol, and readily soluble in oils or acetic acid. Pyrethrin is composed of an acrid, brown resinous substance, which is soluble in alcohol, but insoluble in water and strong alkaline solutions; and a dark yellow oil, which is soluble in alkaline solutions. This oil is not nearly so acrid as the brown resinous matter, and it is probable that what burning taste it possesses is due to a small quantity of the resin being mixed with it.

DIFFERENT METHODS OF TREATING CERVICAL CATARRH.

DR. L'VOFF, of K^{azan}, has reported in the *Meditinskoe Obozrenie* (*Lancet*, January 22,

1887) a number of observations made on the comparative value of different methods of treating catarrh of the cervix uteri. The total number of cases was eighty-two. Of these, thirty-six were treated by mechanical scraping of the mucous membrane, eighteen by means of powerful caustic applications, and twenty-eight with weak caustics. The method of applying the weak caustics was, after washing out the vagina with warm water or a solution of boracic acid, to swab the cervical canal with tincture of iodine or with a ten per cent. solution of chromic acid. This was done once a week, plugs soaked in glycerin of tannin being also used every other day. The strong caustic application consisted of a bougie made of sulphate of zinc and alum fused together. This was allowed to remain in the canal till it had all dissolved, which took place usually in one or two hours. Afterwards the mucous membrane presented a white appearance, due to the eschar. This fell off in five or six days, during which time warm vaginal douches were administered, and plugs of glycerin and iodoform inserted every alternate day. In the cases treated by scarification an iodoform and glycerin plug was left in for twenty-four hours, and the patient was then sent home. The results of these different methods of treatment were that the mild caustics ultimately effected a cure, but required at least two months to do so; while the severer methods—that is to say, the fused zinc and alum and the scarification—produced a permanent cure in about a fortnight. The author adds that no unpleasant symptoms were caused by either the caustics or the scarification in any of the eighty-two cases.

THE ADMINISTRATION OF PHOSPHORUS IN RICKETS.

The administration of phosphorus and of phosphates in rickets has been recommended, on the ground that in the diseased bones the earthy phosphates are greatly deficient, and that, introduced into the system, these substances will supply the deficiency. Phosphorus, as is well known from the researches of Wegner, when given to growing animals, renders the developing cancellous tissue of the bones denser than natural, more like the compact tissue; even in adult animals a similar change takes place. These results are independent, as Wegner showed, of the presence of excess of phosphates, for they occur when phosphates are absent from the food. Although, there-

fore, the reason for the administration of phosphorus in rickets is well grounded, medical men hold very different opinions as to its utility in that disease. Some have given it with cod-liver oil; as in Kassowitz's phosphorized cod-liver oil, which contains 0.01 per cent. of phosphorus. The objection to this mode of administration is not only that the phosphorus tends to deposit on standing, and thus a variable and even dangerous dose may be given, but it is impossible to say how much benefit (if any) that ensues is due to the oil, and how much to the phosphorus. A better mode of administration has been devised by Hasterlik. Phosphorus (0.01 per cent.) is dissolved in bisulphide of carbon (0.25 per cent.), and one hundred parts of water added; 1 teaspoonful is given twice daily, constituting a dose of 0.0001 gramme in the day. The bisulphide of carbon not only acts as a solvent for the phosphorus, but has, according to Dujardin-Beaumetz, a beneficial effect in intestinal catarrh, and might thus be of service in the early stages of rickets. How far this preparation is beneficial in the disease has not yet been sufficiently ascertained.—*The British Medical Journal*, February 19, 1887.

Reviews.

HOUSE PLANTS AS SANITARY AGENTS; OR, THE RELATION OF GROWING VEGETATION TO HEALTH AND DISEASE. COMPRISING ALSO A CONSIDERATION OF THE SUBJECT OF PRACTICAL FLORICULTURE AND OF THE SANITARY INFLUENCE OF FORESTS AND PLANTATIONS. By J. M. Anders, M.D., Ph.D., etc. Philadelphia: J. B. Lippincott Company, 1887.

Those who are already interested in plant-growing will find every page of this work full of interest to them, entirely apart from the question of the soundness of the author's views in relation to the remedial value of growing plants. So thoroughly has he studied the subject, so completely is he absorbed in it, and so practically, that there is scarcely a suggestion of value in regard to house-gardening that he has not given, and the unscientific florist will find his own field of view vastly widened, and to his great advantage, by the wider view of the author, who brings to the work a skill and science already cultivated in a far more trying field.

The question of the value of plants in general upon the surrounding atmosphere may be regarded as pretty well settled, and we must all admit that by them the balance of

nature and the integrity of the air is preserved, but we cannot forget that certain plants are notably injurious to the human race, and a still larger number under suspicion, and that still more, as yet unsuspected, may yet turn out to be hurtful in ways at present unknown. Then there is the question of the diseases of plants, house-plants being peculiarly liable to disease. That a very innocent disease of a plant may be a cause of a very serious disease in another plant is also known. Then there is the question of the sanitary condition of plant earth, the questionable soil in which they are potted, the more questionable but indispensable fertilizers, and the still more questionable fermentation and unseen growth in the damp and often sour soil. All these things and more are worthy of consideration before we rush wildly to the florist's rather than to the neighboring pharmacy when sickness breaks out in our families. Were the rosy view of the author to be applied, we should soon be prescribing carnation pinks and rhododendrons as freely as we now do pills, and the florist on the corner would grow in wisdom and pecuniary stature, while the patient apothecary would dwindle; polypharmacy would have its analogue in the polyflorist, who would order his flowers by the bouquet, and the worse the case the more the floral variety. The whole scheme of course needs practical development, but there is no doubt that the developer would appear, if he has not already. And where, then, would homœopathy be, and its sugar and its dilutions? The floral physician called to an urgent case, say of pulmonary hemorrhage, writes hastily and illegibly for ten monkey-flowers and a magnolia, with six lively pine-trees. The servant hastens to the florist, the florist's boy hastens back with a push-cart, and in a trice the plants are deposited by the bedside of the sufferer. She smiles feebly. The potent influence of properly-selected plant-life, assisted by the active remedial power of scientifically-applied plant perfume, does its work. She is saved! No nauseous doses, but "nature's own remedy," as the specific advertisements put it. How simple and touching, then, the position of the floral physician while the grateful family surround him and present him with the magnolia!

The florists will have qualified assistants, too, for mistakes may happen, and cast temporary discredit on the new system. The physician may order roses; the florist's ignorant clerk may send the tuberose; the patient

may die. All these things will, however, regulate themselves. The very thought of it all as a possibility seems to lift us above the sordid world of drugs, and though the vision may never be realized, we catch a glimpse of an elysium of practice, where the emancipated practitioner flits like a butterfly from flower to flower, and lives in a perpetual atmosphere of plant-moisture, perfume, and ozone. Ozone, ozone, how many theories have flourished in thy name!

The author of "House Plants" has carefully investigated the lives of florists. He finds that the greenhouse is a true sanitarium, and almost proves that the most deeply-seated tendency to phthisis may be eradicated, or held at bay, by leading a "florist's life;" but he also has discovered, or we have, from his account of his researches, that when once the business has been undertaken, it must be carried on to the end. There must be, literally, no looking back after putting one's hand to the plough or trowel, for to abandon the business is to invite death. Even to break a leg, and be kept out of the greenhouse for a few weeks, has been fatal. When such accidents occur, the sufferer, so far as we can see, must be treated in the greenhouse, surrounded by his favorite plants, boneset being probably the most beneficial.

The subject of house plants as sanitary agents involves indirectly the question of the relative value of dry and moist heat. The author argues in favor of a moist heat, which he would vary in its moisture to suit cases of different kinds; but so long as our winter catarrhs are contracted by the rough changes of temperature and by checked perspiration, so long will the transition from a greenhouse atmosphere to our out-door cold be injurious, and more liable to produce disease of the air-passages than a transition from the average dry air of our houses as ordinarily heated. Furnaces have much to answer for, but need not burn the air they furnish us, and need not disseminate the cellar air if properly fitted with cold-air flues. The air of a house should be still far from saturation, and be capable of rapidly drying perspiration from the surface of the body,—so dry that our clothing will be non-conducting, its interspaces being filled with dry air.

These few points of dissent, however, do not materially detract from the high estimate we have formed of Dr. Anders's work. The field is worth working, and so far we know no book on the subject of equal value. The author's style, too, is simple, forcible, and

possesses the homely charm which always accompanies the writing of a true enthusiast, and we recommend all to read it, feeling sure that few will put it down without a positive increase of knowledge in certain lines likely to prove serviceable in their every-day work.

E. W. W.

SPINAL IRRITATION (POSTERIOR SPINAL ANÆMIA).

By Wm. A. Hammond, M.D., etc.

Detroit, Mich.: Geo. S. Davis, 1886.

This is another number of the "Physician's Leisure Library." In it the author gives a careful history of the disease, with its literature. The opening sentence we quote: "Under the designation of 'spinal irritation' I described over twenty years ago an affection to which Americans, and especially American women, are liable to a greater extent than the people of any other country in the world." The eminent author, it will be observed, only described it "under the designation of spinal irritation." He did not invent the term, which he states "appears to have been first used by Dr. C. Brown, of Glasgow." The author's claim rests rather upon his theory of the cause of the affection being a posterior spinal anæmia, concerning which he says that it is better, when knowledge fails, to have some theory than none. His theory he supports by considerable argument, and in his subsequent pages gives us quite complete and graphic studies of the condition, its causes and treatment.

The treatment resolves itself primarily into blisters, which are most successful, and for rapid effect the actual cautery. Internally, he gives strychnine and phosphorus, coca, and general tonics. He considers it a manageable condition, susceptible of improvement generally, of cure often. The treatise is quite complete and useful, but contains nothing especially new at the present day.

E. W. W.

HANDBOOK OF PRACTICAL MEDICINE. By Dr. Hermann Eichhorst, Professor of Special Pathology and Therapeutics, and Director of the Univ. Med. Clinic in Zurich. One hundred and six wood engravings. Vol. II.

New York: Wm. Wood & Co., 1886.

The second volume of this work sustains fully the valuable characteristics which distinguish the first,—clearness, condensation, thoroughness, mark its pages. The condensation, complete absence of redundant words and sentences, complete absence of any style but the direct didactic, is remarkable, and the

time and patience of the reader are much economized. This volume, like its predecessor, starts upon a much higher plane of true scientific medicine than the average manual, or even complete monograph. Taking as an illustration of this the analysis of Part II., on "Diseases of the Œsophagus," we have a careful description, etiology, anatomical changes, symptoms, diagnosis, prognosis, and treatment of stenosis, dilatation, catarrhal and phlegmonous inflammation, corrosive inflammation, round ulcer, cancer, hemorrhages, perforation, spontaneous rupture, softening, spine paralysis, and spasm of the Œsophagus.

The present volume contains also chapters on "Diseases of the Stomach, Intestine, Liver, Pancreas, and Peritoneum." The section on "Diseases of the Urinary and Sexual Apparatus" commences with a very valuable chapter on "Symptomatically Important Changes in the Urine." This is well illustrated, and fully describes the most recent tests as applied to the urine for the detection of albumen and other abnormal constituents. In this chapter, perhaps more than elsewhere, the condensation of the subject-matter is rather a hindrance than a help.

The author, among his general divisions of true albuminuria, makes one between permanent and transitory. The various relations of serum albumen, serumglobulin (paraglobulin), peptone, propeptone are discussed. The best test for serum albumen known, the author says, is the heat and nitric acid test. The ordinary test is described, and also Heller's test, and the acetic acid and heat test. Regarding picric acid, we quote the author's exact words: "If urine which contains albumen is filtered, and an excess of concentrated picric acid is added, a flocculent precipitate will be produced, or, if the amount of albumen is very small, a simple cloudiness." The author does not believe with Cooke and Watkins that picric acid will produce a precipitate in non-albuminous urine which contains quinine or potassium salts. He says, "Peptones can also be recognized with the aid of picric acid. They are also precipitated by the acid; but, unlike albumen, are redissolved by boiling or on the addition of nitric acid." The metaphosphoric acid test will also detect peptones in the same way. All these tests, the author says, "will not distinguish serum albumen from paraglobulin." The latter is detected by saturating the specimen with magnesium sulphate, when the resulting precipitate is paraglobulin. After filtering this out,

the serum albumen is tested in the ordinary way. Propeptone: the urine is clear on boiling, cloudy when cold, if acetic acid or nitric be added, and clear again when warmed.

Chyluria is divided into tropical and non-tropical. In the former only has the filaria been discovered; in the latter "nothing is known concerning the genesis of the disease."

The author describes "Oxaluria" as a disease which exists in the minds of "English writers," and denies that there is such a "distinct disease of nutrition which leads to increased excretion of oxalic acid in the urine," and disposes of the matter by saying that it is observed after the ingestion of grape, spinach, celery, rhubarb, etc. The illustrations of "Diseases of Renal Parenchyma" are also full and excellent. Four illustrations exhibit the eye changes in renal diseases. The volume ends with a chapter on "Diseases of the Male Sexual Apparatus," and an appendix on "Diseases of the Supra-renal Capsule."

E. W. W.

A PRACTICAL GUIDE IN ANTISEPTIC MIDWIFERY IN HOSPITALS AND PRIVATE PRACTICE. By Henry T. Garrigues, A.M., M.D., etc.

Detroit, Mich.: Geo. S. Davis, 1886.

We have already had occasion to notice favorably several volumes of the "Physician's Leisure Library," among others the "Modern Treatment of Ear-Diseases," "The Use of Electricity in the Removal of Superfluous Hairs, etc.," and the two volumes entitled "New Medications." The great value of these publications, their handy and attractive form, excellent paper and type, and extremely reasonable price, twenty-five cents per volume, all commend them. They are new and original works of a high order, filling a place entirely apart from that occupied by other library and serial medical publications, and they deserve the widest recognition. The book of Dr. Garrigues on "Antiseptic Midwifery" is thorough and complete. And it probably often happens that the echo of what the great medical world is doing may be but faintly wafted to the rural practitioner, to his city brother immersed in the anxieties of general practice, and that, although the general facts are known to them, and perhaps the discussions of societies listened to and the published papers read, yet still they have but a faint and unreal idea of what perfect antiseptics is, in its recent adaptations. To such we especially recommend this work. It is a working manual. Any one possessed of average professional training can

easily and without expense practise it as well perhaps as the author. If any fail to realize its value, let them study Dr. Garrigues's book carefully, con his arguments, and read his results, and then calmly and dispassionately ask themselves whether it is not worth while to try it.

The argument that it is a good thing for hospitals but unnecessary for private practice is attacked by the author with great spirit and apparent success. He proves, or thinks he does, that under antiseptic lying-in is safer to-day in hospitals than it is in private practice without such precautions. He says, "Now the lying-in hospitals have become the safe places to be confined in." Of those who point to their thousands of deliveries without a case of puerperal fever he remarks, "Either their memory fails them, or they have a convenient definition of puerperal fever, in consequence of which puerperæ die of peritonitis, metritis, pneumonia, pleurisy, heart-disease, liver-complaint, kidney-trouble, meningitis, etc., but never of septicæmia." There is much force in the author's comment that if notes were kept of every case the mortality would somehow not be far from one in a hundred, and he thinks that the personal interests of the practitioner should be sufficient alone to force him to adopt the method of which he writes.

The expense and trouble of antiseptic when enforced among the poor in private practice are, the author thinks, very little. Ignorance rather than poverty is the opponent. The expense reduced to its lowest figure is carefully calculated, and amounts to one dollar and forty-four cents per patient, and this he considers is amply repaid in the diminution of necessary visits, the absence of protracted illness, and intercurrent complications.

But many who will decline to take what they consider useless trouble, if employed as a routine practice, would willingly avail themselves of the strictest antiseptic in special cases when confronted with the ominous symptoms of septic infection. The practitioner who has employed it daily will be familiar with its routine; but, if an inexperienced, some such book as this will be invaluable to him, for the author possesses the happy, if rare, faculty of clearly describing all his procedures in the simplest and plainest language. The description of the minute treatment of a patient, showing diphtheritic wounds of the vagina after delivery, will give the readers a good idea of the author's power in this line. In short, while we are unwilling to enter on

the question of the absolute necessity of so much care in all cases, none can doubt its value in special ones, and for this reason, if no other, we commend the book to all readers.

E. W. W.

THE PHYSIOLOGICAL, PATHOLOGICAL, AND THERAPEUTICAL EFFECTS OF COMPRESSED AIR. By Andrew H. Smith, M.D., etc.

Detroit, Mich.: Geo. S. Davis, 1886.

This volume of the "Physician's Leisure Library" contains a careful study of the effects of compressed air, as witnessed by the author while physician in attendance on the men working in the caisson employed in building the Brooklyn Bridge. As a practical study it is of great value, and may be said to afford the basis from which to estimate the value of the employment of compressed air therapeutically in the pneumatic cabinet and in other ways. The caisson was not devised as a therapeutic agent, and therefore is not liable to be under- or over-estimated. Dr. Smith has performed his part of observer and experimenter with great care and judgment, and his book deserves to be a standard authority on the subject. It is from such cases as he narrates, carefully studied as he has studied them, that great discoveries arise, and a leisure hour will be well spent in reading his carefully-written account.

A REFERENCE HANDBOOK OF THE MEDICAL SCIENCES. Edited by Albert H. Buck, M.D. Volume IV.

New York: William Wood & Co., 56 and 58 Lafayette Place, 1887.

We have already noticed in detail, as they have appeared, the previous volumes of this great and most useful publication. The present volume commences with the subject of "Ichthyol," and closes with a discussion of "Milford Springs." It appears to us to be in all respects equal to its predecessors, and confirms us in the opinion that, when completed, the "Reference Handbook" will furnish a most valuable book of reference to the general practitioner of medicine, giving him full and reliable information upon almost all conceivable subjects connected with the profession, and especially valuable for its full accounts of the various springs and health resorts of America. The illustrations are on a par with those of the other volumes. The lithographs comprise one representing test-tubes containing various growing bacilli, and showing quite well the peculiar characteristic forms of the colonies. This plate differs from most of its predecessors in having some prac-

tical value. On the score of æsthetic beauty we can commend Plate 17, which consists of various representations of carcinoma and sarcoma of the larynx. No amount of red and yellow ink has been spared in adorning this sheet of paper. If irregularity of outline, abundance of paint, and general hideousness of appearance can warm the hearts of subscribers, Plate 17 should be a success. Possibly it may be useful to some one, but such individual must be an extraordinary medical production.

HOT-WATER AND BEEF PLANS IN CHRONIC DISEASES.

This little book is an exposition of the peculiar method of treatment of chronic diseases devised by Dr. James H. Salisbury, now of New York City, who during the war of the Rebellion obtained notoriety by his alleged discoveries of the causes of measles, malaria, etc., discoveries which were founded on ignorance, but which for a few months obtained some acceptance through the credulity of the profession.

The present work indicates that the exponent of the Salisburian plan is no more learned than is its author. When we read that hot water washes down the "slimy yeast" of the alimentary canal, and that diseases of fatty degeneration and paralysis are due to the absorption of carbonic gas, we are enabled to diagnosticate the mental condition of the writer. Nevertheless usefulness attaches to the book, as revealing fully a method of treatment which was for a time "a rage" among certain people, and which in some cases really may be useful. Some physician whose statements are worthy of credence ought to go over the subject. We would very much like to know whether it is true, as is asserted in this book, that the sipping of half a pint of hot water of 110° to 150° Fahrenheit before each meal will cause the feces to become black, and alter markedly the constitution of the urine. By the way, it seems to us that it must be a well-trained throat which can drink water of 150°, the high limit of the Salisburian plan.

We can testify from our own experience that in cases of feeble digestion the meat-ball, made by scraping the pulp out of a beefsteak, and forming a mass like a sausage-cake, and then broiling, affords a most excellent article of diet. The American meat-chopper, manufactured at Athol, Mass., makes a very excellent substitute for the case-knife and the hand, and makes it possible to prepare these meat-balls without much labor.

The directions for the use of these choppers and for the methods of cooking in the little book are good, but are unnecessary. The choppers themselves contain all the necessary printed directions, and any good cook ought to know how to broil a meat-ball after one or two trials.

A TEXT-BOOK ON SURGERY, GENERAL, OPERATIVE, AND MECHANICAL. By John A. Wyeth, M.D.
D. Appleton & Co., New York, 1887.

The above work we have read, and will judge it from its title, viz., "A Text-Book on Surgery," or, in other words, a book to teach from; but may we not also look at it from the opposite side, and consider it a book to learn from? In answer to the first of these definitions, we do not hesitate to say that Prof. Wyeth has given us a most excellent book, one in which will be found all the advances of modern surgery and all that is good of older surgery. If at times the text is found too brief,—and from the scope of the work this must occasionally occur,—we have at least a suggestion, which may be further elaborated by referring to the more exhaustive encyclopædias or systems of surgery. The more important question to answer is in regard to the value of the book as a means of obtaining surgical knowledge, and, indeed, it is in this sense that the title of the work must be mainly considered. Again do we answer in the affirmative, and believe of the many text-books which are in use by the medical colleges, none are better, few are equal, and many are inferior; therefore we hope to see this work of Prof. Wyeth's recommended to those beginning the study of surgery, since we think a good foundation to build up a knowledge of the science and art of surgery may be found in it.

The question of surgical dressings is decided by Prof. Wyeth without any discussion, and we are also of the opinion that the time has now arrived when such discussions are unnecessary, believing, as we do, the final decision has been determined, and those surgeons who still obstinately, in the face of every-day facts, refuse to adopt antiseptic methods of treating wounds, are not practising surgery as a progressive science, and are not doing the best for the unfortunate patients who may place themselves under their care. The subject is, very properly by Prof. Wyeth, settled in a single paragraph, as follows: "This practice (antiseptic), which embodies the great principles of *cleanliness* and *carefulness* in surgery, is now so well

established among the best surgeons in America and Europe that any argument in its favor, as compared with the methods of one or two decades ago, I consider to be wholly unnecessary." The directions and various substances employed in order to carry out the antiseptic practice are briefly but satisfactorily given.

Under hydrophobia the author mentions the recent investigations of Pasteur, and states that this scientist claims he has "cultivated the specific germs of this disease, and through inoculations with the cultures immunity from rabies may be secured." This, we believe, is an error. Pasteur, so far as we know, did claim to have isolated the specific germ of hydrophobia, but later he denies having succeeded. While believing the disease to depend upon a specific germ, he has as yet never been able to demonstrate it, although many investigations were made in order to determine this question. The inoculations made by Pasteur on man, to prevent the development of this disease, have all been done with the spinal cords taken from rabbits, the latter having been inoculated from an animal said to have the disease transmitted to it by inoculation originally from a rabid dog.

The chapter on amputations has impressed us very favorably, and, with the author, we believe this surgical operation is becoming less frequent than before the antiseptic methods were employed. He writes "that in the present rapid advance in the science of surgery, and the great perfection in its art, the time is not far removed when amputations for other cause than gangrene will be comparatively rare." This is saying much, but when we look back and see what has been done, we cannot but anticipate a realization of the author's view. The methods of operating are concisely given, and leave no room for comment. Preference is given to the *solid-flap* method, viz., a flap composed of all the soft tissues lifted from the periosteum. The reasons why this method is to be preferred are stated by Prof. Wyeth as follows: "That flap will unite most readily, and prove most satisfactory, in the formation of which the normal relation of the skin to the subcutaneous soft tissues is least disturbed. It is always preferable to divide the skin, muscles, vessels, and other soft tissues squarely across and not obliquely, as must of necessity be done in forming flaps by transfixion. This method is applicable to most amputations." The illustrations showing the transverse sections of the extremities at different locations,

which have been copied from Prof. Braune's work, add much to the value of this chapter.

The article on surgical diseases of the vascular system differs from the other portions of the work, in that we have in it not a text but a very exhaustive treatise upon the subject. This is explained by the fact that it was written for and appears in the "International Encyclopædia of Surgery," and it is a most able exposition of these lesions, but we think it would have been better if the author had made it conform to the other portions of his book, since it contains much that is not amiss in an encyclopædic article, in truth necessary for it, but could with advantage be omitted from his present work. The important operation of "ligation of arteries" has been presented in a most masterly manner, and we cannot speak too highly of this portion of the book; more especially are the illustrations, which are so necessary in order to intelligently and readily understand these operations, to be praised. They may be called beautiful; indeed, the only objection we can make is that the artist has given us a too charming picture. To see the vital regions of the neck exposed by a most minute dissection, and have the face presenting a smiling, happy expression, the eyes open and sparkling with pleasure, is very pretty, but, in truth, unnatural.

Fractures are presented to us with all the modern and best methods of treatment. The directions given to properly obtain a favorable result in these frequent lesions are such as we can fully concur with, making, however, an exception in that of fracture of the femur. The choice is given between extension and the plaster of Paris dressing, and preference given to the former. In our opinion there is no choice, believing, as we do, that there is but one method, viz., extension; and to sustain this we quote the late Prof. Hamilton, who wrote as follows: "The plaster of Paris is not a safe or judicious dressing for fractures of the thigh, either for fractures through the shaft or for fractures near the upper or lower extremities of the bone, for fractures in children or in adults, for compound or simple fractures." We notice that Prof. Wyeth strongly condemns the recently introduced method of treating fractures of the patella by opening the joint and wiring the fragments together. This procedure is also in our opinion a rash, dangerous, and uncalled-for method, and we believe with the author, who says, "A careful observance of the rule of practice just laid down will secure a liga-

mentous union, with a restoration of the function of the extremity, equally as good in many cases as that enjoyed before the injury, and in the vast majority of cases equal to all the ordinary requirements of the limb, and this is accomplished without the slightest risk to the patient's life. . . . On the other hand, although an osseous union may, in the majority of cases, be obtained, the restoration of function is not more complete, the confinement to bed is longer, and the danger to life and the integrity of the part sufficiently great to deter the surgeon from employing this method (wiring) of practice."

Prof. Wyeth is not yet willing to accept the views of most German and some French surgeons in regard to the etiology of non-traumatic osteitis. He admits that tuberculosis is frequently a cause of osteitis, but thinks the non-tubercular form to be more frequent. Our own experience and reading upon this subject would incline us to the tubercular side of the question; at least we believe many obscure cases are better explained by this view than by any other. The directions given for performing exsection of the knee-joint, especially the use of the author's drills, to transfix the bones, are to be recommended. The chapter on abdominal surgery is well abreast of the period, and advocates, or at least describes, the various operations which have within the past few years been proposed, some of these, in our opinion, being nothing more than ante-mortem dissections, and as such should find no place in surgery. The reasons in favor of operative interference in wounds of the abdomen, given by the author, are quite convincing, and only further confirm our own views in regard to this method of treatment. He says, "1. The enlargement of a wound sufficiently to demonstrate its opening (or not opening) into the cavity of the peritoneum is a simple procedure, practically without danger. 2. Abdominal section is not difficult, nor, when skilfully and properly performed, a dangerous operation. 3. A penetrating wound of the abdomen, left without surgical interference, is attended always with great danger. 4. If any vessels of size are divided, hemorrhage is an immediate danger, and peritonitis a serious and probably fatal complication. 5. If the alimentary canal is opened, death is almost inevitable. The few recorded cases of recovery form such an infinitesimal proportion of the whole, that they should carry no weight against interference."

The descriptions of the surgical lesions of

the genito-urinary organs and their treatment are somewhat brief, but all essential points are included in the context. Venereal diseases have received due attention, and a rational method of treatment is advised; syphilis being properly considered a curable affection, provided suitable medication and sufficient time are given to its treatment. In the treatment of stricture of the urethra, internal urethrotomy is advised, as being better adapted to most cases, in so far as the chances for a permanent recovery are reasonably good. This opinion we are in accord with, but our practice in the treatment of this lesion has been first to employ gradual dilatation, and if all symptoms disappear in a reasonable time, no more is done; that there will not be a return of the trouble we cannot foretell,—probably sooner or later there will; however, we think in some cases there has been no further difficulty. We have at least given an opportunity for mild means to overcome the disease. If not successful, we then resort to more severe measures, and perform internal urethrotomy, after the method given by the author, which is essentially that introduced by Otis. The concluding chapters, on deformities and tumors, are in keeping with the rest of the book, and ably represent the modern methods and views in regard to these lesions.

Prof. Wyeth is certainly to be congratulated for the manner in which his publishers have done their part. The illustrations, the paper, the typography, and in fact the entire work may be regarded as a beautiful specimen of the art of book-making. J. H. C. S.

Correspondence.

BERLIN.

(From our Special Correspondent.)

In accepting with pleasure the invitation of the THERAPEUTIC GAZETTE to furnish its readers, in a series of letters, a *résumé* of the scientific life and activities of the German capital, it is my purpose first to describe briefly the condition of medicine in Berlin.

The centre of scientific ambition in Berlin is the University, of whose four faculties the medical only is at present pre-eminent.

This faculty is, however, the most distinguished in Germany. We need only mention the names Virchow, DuBois-Reymond, Helmholtz, Leyden, Gerhardt, Von Bergmann, Waldeyer, Liebreich, Schroeder, Gusserow, Westphal, Robert Koch, to recognize those upon

whom depends the fame of this celebrated institution. The most important of the subdivisions of the medical department of the University are the Pathological Institute, the Department or Institute of Physics, the Physiological Institute, the two Clinics of Internal Medicine and the Clinics of Surgery, the Anatomical and Pharmacological Institutes, the two Obstetric Clinics, the Clinics for Psychiatry, the Hygienic Institute. From these have emanated the conclusions drawn from researches which have influenced the medical knowledge of the world. The principal instructors hold the positions of directors of the institutes and clinics; the latter, excepting some which occupy new buildings especially constructed for them, are held in the oldest hospital in Berlin,—the Charité.

There are in addition a large number of hospitals which afford material for study and publication. Among these are the two large city hospitals, the Friedrichshain and the Moabit. A second nucleus of medical life are the medical societies of Berlin, the chief of which is the Berlin Medical Society, with Rudolph Virchow at its head: it numbers over six hundred members. Next in importance is the Society for Internal Medicine, with Leyden and Gerhardt leading its clinics. The surgeons meet in a "full assembly," which meets monthly, generally at the clinic or hospital wherever there may be an interesting case for demonstration. In addition there are the Gynæcological and Obstetrical Societies, the Society for Hygiene, the Society for Psychiatry and Nervous Diseases, the Physiological Society, the Society for Dermatology, and the Society of the Physicians to the Charité. All meet weekly, fortnightly, or monthly, and number from fifty to three hundred members. In these meetings there are valuable scientific discussions, and I shall have frequent occasion to revert to them in future. The official accounts of these societies are published in the special *Archiv*, and the monthlies of the Berlin Medical Society, of the Society for Internal Medicine, in the *Berliner Klinische Wochenschrift*, and the *Deutsche Medicinische Wochenschrift*, two of the most important of German medical publications, and edited in Berlin. In addition to the four societies mentioned, there are in Germany a number of associations which include the societies of the empire. Aside from standing societies which do not come within the scope of these letters, as taking place in the first rank of these is the Society of German Naturalists and Physicians, which

meets yearly in different places of Germany, and whose discussions open a wide field. Next in importance are the Congress of Surgeons, which meets in Berlin yearly, and the Congress for Internal Medicine, whose place of meeting is Wiesbaden. Accounts of the proceedings of these three great societies will be included in my letters.

It will be of interest to know that Professor Ehrlich, assistant in the clinic of Professor Gerhardt, has recently treated a number of cases of typhoid fever which occurred in the clinic with thallin, with most beneficial results: the details have been given in the medical journals. Following the results obtained in the clinic of Professor Leyden, antifebrin has been used with good results in acute joint-rheumatism by Müller in Gerhardt's clinic. He gave 30 grains daily for several days, and observed in some cases the cyanosis which Cahn and Hepp have reported. A moderate degree of uræmia was observed in some cases, and spectroscopic examination of the blood showed a methæmoglobin line. On shaking the blood with air the line did not disappear, showing that a portion of the coloring-matter of the blood was unfit to be oxidized by respiration. The blood examined was light brown in color. After the withdrawal of the drug a trace of the substance remained for several days. Müller concluded that a portion of the antifebrin became anilin in the body, and as such was injurious.

At a meeting of the Society for Internal Medicine, January 10, Dr. Harrlich, assistant in Leyden's clinic, spoke of salol, as recommended by Nencki and Sahli. He had used the drug in twenty-three typical cases of acute joint-rheumatism, in some cases of chronic joint-rheumatism, in a number of cases of acute muscular rheumatism, and in the doses given by Sahli—3iiss to 3ii—he had observed favorable effects following its use, and he had been led to believe that the carbolic portion of the compound drug was of especial value, as the results indicated a greater potency than could be attributed to salicylic acid alone. The drug was well borne, without inconvenient after-effects. It was given in powder, in wafers or tablets, 30 grains at a dose. Salol did not prevent endocardial complications or relapses; it was especially useful where high temperature was present, as is true of all antipyretics in rheumatism.

In a meeting of the Berlin Medical Society of January 19 Dr. Bidder described his method of aborting furuncles, a subject not new in literature, but regarding which extensive ob-

servations have not developed a fixed plan of treatment. Bidder began his treatment in 1875 with one hundred cases, which gave favorable results. His plan consists in the injection with a hypodermic syringe of a two per cent. solution of carbolic acid obliquely into the furuncle at one side; a second injection is made upon an opposite side; both go to the centre of suppuration. A few drops are given each time. In addition a compress wet in carbolic solution is placed over the furuncle, and when this cannot be used mercurial plaster is substituted. A repetition of the injections is not generally needed, and is not thought desirable. Furuncles so treated do not generally open, but are dissipated. In small furuncles the injection of a few drops suffices; in the larger ones two injections of half the contents of a Pravaz's syringe were enough; in the largest, as large as half a human hand, four injections of half or the whole syringe were given. When a condition of furunculosis was present, as sometimes occurs in diabetes mellitus, constitutional treatment was imperative. In contrast with the foregoing, Dr. Bidder treats felons by incision.

Dr. Lassar stated another method of treating the same affection. Recognizing the fact that the skin over the centre of a furuncle is thin, and that through this skin access is obtained to the pus beneath, Lassar has used very small spoons, as large as a needle, which have enabled him carefully, and without giving pain, to remove the contained pus from the centre.

PARIS.

(From our Special Correspondent.)

Salicylated Aliments before the Academy of Medicine.—The fact that the French Academy of Medicine has condemned the use of salicylic acid as a preservative of aliments is probably now well known; but the reasons which led to the decision are scarcely less important than the decision itself. They were elicited during the debates preceding the vote on the committee's report, and deserve careful consideration.

Dr. Constantin Paul, when the report was read, first entered the lists by breaking a lance in favor of salicylic acid. Admitting the occasionally untoward effects of the acid and its compounds when administered in therapeutic doses, he denied their danger in small quantities. He quoted the experiment of Dr. Kolbe, the discoverer of the artificial

acid, who took for thirteen months 1 gramme ($15\frac{1}{2}$ grains) of salicylic acid every day without being inconvenienced, that of Dr. Lehman with $\frac{1}{2}$ gramme daily, and others related by Raynaud and Oulmont. Dr. Constantin Paul's conclusion was that salicylic acid is an excellent and harmless preservative of aliments; that if its use be forbidden the aliments now preserved by its help will reach the consumer in a spoiled condition, and that it is better for the public to partake of salicylate than of spoiled aliments. In consequence, he was in favor of strictly limiting the proportion of acid allowable. From the start Dr. Paul was evidently at a disadvantage, having to prove a negative proposition, namely, that salicylic acid is not dangerous.

Dr. Vallin replied that if few accidents due to salicylic acid have so far been observed, it is because physicians have not looked for them. When they have a dyspeptic patient, how often do they examine his aliments or his urine for salicylates? If there were distinct symptoms of intoxication, perhaps attention might be awakened. But we often see even such characteristic affections as chronic lead-poisoning mistaken for anæmia or cachexia, until some keener observer notices the blue line on the gums, showing the real cause of the trouble. The danger of salicylates is greater for valetudinarians than for persons enjoying robust health. If their use is tolerated at all, everything we eat and drink will contain some of the chemical, for it is a great deal cheaper to preserve a twenty-five-gallon cask of wine or beer with ten grammes of salicylic acid worth four cents than to employ sufficient care, cleanliness, and good materials in the manufacture. The same remark applies to other aliments.

Dr. Constantin Paul admitted that care, cleanliness, and good materials are preferable to salicylic acid, but maintained the innocuity of the acid, since there are no positive records to the contrary.

Dr. Brouardel now taking the floor, said he had made some personal experiments throwing light on the subject. Having alluded to the acknowledged danger of salicylic acid to aged persons, or those suffering from impairment of the renal or digestive functions, he related the following results arrived at in experiments made by Dr. Bouchut and repeated by himself: "When a small dose of salicylic acid, say 20 centigrammes (3 grains), is daily administered to a young man of 20, a man of 50, and an old man of 70, on testing the

urine the characteristic reaction of salicylic acid will not be detected in the first specimen because the acid is transformed in the economy as it is absorbed; the same thing will often occur with the second, but never with the third subject. The acid will be still present in the urine of the third—the old man—several days after the administration has ceased. Hence it follows that if the dose be kept up for some time, salicylic acid will accumulate in the economy, and, in case of renal lesions, serious accidents may result. It is difficult and often impossible to determine the cause of such accidents, because they resemble so much those due to cerebral or gastro-intestinal troubles, and I incline to think the evil is of more frequent occurrence than is generally believed. Within the past ten years my associates and myself have made more than three hundred post-mortems at the morgue in cases of sudden deaths. In more than one-half of them death had been caused by arterial sclerosis, and often the renal lesions due to this disease had occasioned the suddenness of the death by impeding the elimination of alcoholic beverages and even medicines administered. The symptoms observed during life, viz., coma, convulsions, cephalalgia, etc., had rendered the inquiry necessary. I do not mean to say that salicylic acid had killed these patients, yet I cannot believe that the chemical would have been free from danger to them, and I am so much the more of this opinion because the slightest excess for such subjects, a bottle of champagne, for instance, is sufficient to cause death. Still, I would not for this reason forbid the use of champagne."

Dr. C. Paul. "Such would be the logical conclusion."

Dr. Brouardel. "Not at all, because when you drink a bottle of champagne you know what you are doing, and when you swallow salicylic acid in your food you do not know it. The danger lies in the underhanded addition. If salicylating be allowed, there will be no limit to the dose absorbed in a day. All aliments, solid as well as liquid, being liable to have their little seasoning with salicylic acid, a man may very easily in this way take from one to two grammes in twenty-four hours. And those who are the most affected by the acid are the very ones whose kidneys cannot eliminate, and thereby will not show the presence of the dangerous chemical. It must not be forgotten that every year fifty tons of salicylic acid are sold and used for preserving alimentary substances. Here is a real danger against which the Academy should

protest by adopting the committee's conclusions."

The committee's report was, of course, concurred in by a large majority,—nearly a unanimous vote.

Dangers of Santonin.—Dr. Laure, at a recent meeting of the Lyons Medical Society, related an interesting case of santonin-poisoning. On December 25 last he was called to visit a child $3\frac{1}{2}$ years old. The parents attributed the evident intoxication to some black lead which the child had daubed over his lips. As black lead, notwithstanding its name, consists of nearly pure carbon and contains no lead, the case was somewhat obscure. The patient was lying on his back, in a state of deep prostration, now and then interrupted by sharp cries. The child then would bend up its knees, and place its hands on its abdomen, apparently the seat of the pain. This fit over, he would fall again into the former somnolence. The face was of a livid paleness, the pupils dilated, breathing frequent, the pulse rapid and irregular, while the rectal temperature remained below 37° C. (98.6° F.). The stomach would immediately reject anything ingested.

Matters passed by the patient after the administration of a purgative enema, advised by the family pharmacist, showed nothing abnormal, excepting the deepened coloration of the liquid portions, and this was at first attributed to the drugs themselves from which the enema was composed.

On the whole the symptoms were very perplexing, when the mother, on being interrogated again, remembered that *two days before* she had given the child a dose of 10 centigrammes ($1\frac{1}{2}$ grains) of santonin. She even had a second powder like it, but, fortunately, did not administer it. It appeared, also, that the day before calling in the physician the child had passed what the parents thought to be bloody urine. This color, Dr. Laure thinks, was simply due to santonin, as Wood states it to be the case finally.

Perhaps the worst symptom was the complete retention of urine, none having been passed within twenty-four hours. But once the case was clearly understood, the treatment was easy and the recovery rapid. A warm bath and a laxative enema restored the flow of urine, and a copious passage relieved the abdominal tympanitis. In a few days the patient was well again.

This custom of dosing children with santonin seems to be a common one with the

French working classes. As soon as the little ones have the slightest diarrhoea caused by teething, some parents conclude they have worms, and give them the medicine without any medical advice. Besides, they administer it simply powdered, without adjuvants or correctives.

As regards the dose of santonin, Dr. Laure thinks the rule laid down by Benzinger, viz., as many grains as the child has years, four days in succession, is one that should be regarded with suspicion. He prefers Wood's advice,—not to exceed one grain for a child less than two years.* Dr. Laure is also of opinion that it is very desirable to combine santonin with a purgative; calomel, for instance. As to the antidotes of santonin, ether, and especially chloral, have been recommended as the best by Becker and Binz. In a case when convulsions or nervous troubles occur, they would have been used willingly. But in the case just narrated it was thought more advisable to facilitate the elimination of the poison by the kidneys and bowels, and afterwards to administer tonics.

Sulphate of Zinc in Epsom Salt.—The appearance of magnesium sulphate resembles so much that of zinc sulphate that there is always some danger of the two salts becoming accidentally mixed together. A little sulphate of magnesium in a sulphate of zinc lotion would probably matter but little. In a dose of Epsom salt, on the other hand, 10 or 15 grains of white vitriol are exceedingly undesirable. A very simple test, recommended by M. Machelart, a pharmacist of Lille, will obviate all danger from this cause. It consists in the addition of ferricyanide of potassium to a solution of the suspected sulphate. Pure sulphate of magnesium is not affected by the test, while sulphate of zinc affords a dirty yellow precipitate that can be noticed even when only two per mille of the contamination is present. As red prussiate of potash is to be found in most pharmacies, it is easy to thus prevent the occurrence of accidents, or rather their recurrence, for it seems they have happened before.

Unexpected Death of Prof. Bécclard.—Dr. Jules Bécclard, a professor of physiology at the Paris Faculty of Medicine, and the dean,

or president, of the Faculty, died on February 9, after an illness of only eight days, at the age of but little over sixty-eight years. His father, who was a native of Paris, like the son, and a professor of anatomy at the Faculty of Medicine, died when Jules was but seven years old. The widow later on married Dr. Ferrus, also a professor, by whose advice young Bécclard applied himself to the study of mental diseases, and became an interne at the Charer-ton Hospital. But on obtaining his diploma he preferred physiology, anatomy, and laboratory investigations. Having become an *agrégé* (fellow of the Faculty) in 1844, he lectured on anatomy and physiology from 1845 to 1859, and afterwards devoted himself to original researches. He was elected a member of the Academy of Medicine in 1862, its perpetual secretary in 1873, and dean of the Faculty in 1882. Dr. Bécclard's writings are numerous and important. For years he was connected with the *Gazette Hebdomadaire*, *Archives de Médecine*, Dechambre's *Encyclopédie de Médecine*, etc. His treatise on "Human Physiology," published in 1855, is now a classical work in the hands of most students. Among his other publications the following may be quoted: "Système Cartilagineux" (1864); "Eléments d'Anatomie Générale," by his father, a new edition (1851); "Hygiène de la Première Enfance" (1852); a translation, with Dr. Sée, of Kolliker's "Treatise on Human Histology," from the German, etc.

PARIS, February 18, 1887.

CHEMICAL FEEDING.

(From an Occasional Correspondent.)

To the Editors of the THERAPEUTIC GAZETTE:

SIRS:—The spirit of self-sacrifice with which American physiological chemists, so called, are endeavoring to build up the failing digestion of the American people is one which needs no commentary or laudation on my part. Its fruits speak for themselves. Are not their praises, or, at least, their taste, in everybody's mouth? What with pepsin, pancreatin, extract of pancreas, papoid, beef extracts, peptonoids, peptogenic powders, condensed milks, juices and extracts of fresh flesh, health foods, gluten bread, and compounds, principles, extracts, and adornments too numerous to be mentioned, the suffering Americans are in a fair way to be sustained in their vital functions, and there is reason to hope that the time will come when, the gynæcologists having removed all the abdominal organs, the lightened body, artificially fed,

* It must be borne in mind that when modern French writers use the term "grain," which, fortunately, they seldom do, they mean five centigrammes, while the English grain is equal to about six and one-half centigrammes.

may go on its way rejoicing through years of usefulness.

Of all these remedies, I would like to call the attention of your readers especially to peptonoids, of which the most recent addition is lobster peptonoids.

"Lobster peptonoids" represents the very flower of chemical research. Beef, mutton, pork, and chicken peptonoids, Thanksgiving peptonoids of turkey, Western peptonoids of bear and buffalo meat, the Southern (colored) "possum peptonoids," but the invaluable lobster peptonoids languish for want of a suitable introduction. By a true flash of genius it is brought to our notice in a series of diet tables or leaflets, whereon are printed the regulation diet for the different diseases. The diet tables are originally, "as revised by leading physicians in Australia and New Guinea," quite free from suspicion, and represent the accumulated wisdom of the profession. All that the inventor of lobster peptonoids had to do, in order to render them worthless, was to print on each leaflet, in a prominent place on the list, "lobster peptonoids." We do not deny the value of these peptonoids, but it is hard to believe that they are so universally valuable in every disease. In some diseases, notably in cholera infantum and varicella, they have undoubtedly achieved great results, especially when associated with terrapin peptonoids. There is the direct argument of common sense for their use, since both lobster and terrapin are water-fowl, and cholera infantum is characterized by watery discharges, and varicella by a watery eruption. Even in gonorrhœa, which affects the water-passages, and in cystitis they might be tried with some hope, and in ascites, but we must protest when we find them recommended in such serious and prevalent diseases as scabies and parotitis.

When the products of real digestion are suspected, under slight deviation from the normal, of becoming deleterious, when a man may be actually poisoned by the products of his own digestive apparatus, it beseeches us to be cautious in employing these new peptonoids. Already pepsin, time-honored pepsin, is under "suspicion of blood-poisoning." It always had a guilty smell, like old anatomical specimens, and an ancient and corpse-like taste, but the world took it at our valuation, a sign of that childlike confidence that the world has always displayed towards us. But now men and manners are changing, and as men no longer take theology from the priest without gainsaying, soon they will hew out for themselves new systems of medicine and

pharmacy. Where, then, will the lobster peptonoids go but into the world's lumber-room, with celery and coca, cerebro-stimulators, liquid foods, "each teaspoonful representing a pound of steak, one chop, six eggs, and half a dozen raw oysters, with a loaf of stale bread," and the thousand and one *quasi* remedies which chemical and pharmaceutical ingenuity devise and force upon us daily and hourly, which cover our desks and tables, are thrust upon us by overzealous agents, and even steal insidiously upon us through the daily post. They fill and distract our waking and sleeping hours till they crowd out the ancient, established, and valuable remedies, tormented and perplexed by the cloud of phantasmal ones which encircles us. And not only us, but the general public, for their circulars flutter on the door-steps of private residences, and come by mail to citizens guiltless of medical knowledge, all extolling the marvellous effects of their elixirs, their nerve invigorators, their wonderful newly-discovered tonics. It will soon be a necessary rule never to employ a remedy so introduced, even though by so doing we shut the door on that most invaluable preparation, the "lobster peptonoids."

URTICARIA FROM INDIGESTION.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—Will you, or some of our scientific men, tell me why it is that indigestion, characterized by burning in the stomach, with sour or bitter eructations, after meals, will cause an intolerable itching, generally, of the whole cutaneous surface between the knee- and ankle-joints, but sometimes in spots, and nowhere else? I have been applied to occasionally, for the last eight years, by men of middle age, for treatment of this trouble. I had several cases before I suspected the cause, and was not thoroughly satisfied till, experimenting upon myself, I found that a cup of strong coffee three times a day, or a tablespoonful of distilled liquor for two days, would make my legs itch so that I could find no rest till I had thoroughly rubbed with table-salt, and then I sometimes use carbolated glycerin. The rubbing with the salt is a perfect luxury. As before said, it is confined to men of middle age; have never found a case of it in the opposite sex. Now, what I want to know is, why this disturbance of the stomach is telegraphed by the nervous system to this distant locality and nowhere

else? I ask for information, private, or, if you think best, through the columns of the GAZETTE.

Yours, etc.,
R. L. HINTON.

PRESCOTT, ARK.

[It is perfectly well known by every practitioner that gastric or gastro-intestinal irritation will produce urticaria and other dermal eruptions or irritations. There is, therefore, nothing novel in the experience of our correspondent. He is mistaken in supposing that the thing is confined to men, or is more frequent in men than in women, excepting in so far that men more frequently over-indulge themselves in the pleasure of eating and drinking than do women. The skin-trouble is undoubtedly produced in many of these cases through the intervention of the nervous system, the irritation of the gastric nerve being reflected to the distant surface of the body. In some cases, however, there is probably absorption of a poison produced in the fermenting mass in the stomach or intestines. In other instances the gastric irritation and the disorder of the skin are the results of a common cause. The symptoms detailed by our correspondent are especially apt to occur in gouty people, in whom a little excess at the table will provoke an outbreak of acid dyspepsia, which is largely the expression of a gouty condition in which the tension is habitually so great that a little more irritation provokes a gouty discharge. In the great majority of cases a pruritus is gouty, but when occurring in middle-aged women, it may be a climacteric phenomenon.—EDS. THER. GAZ.]

POTASSIUM BROMIDE IN SALIVATION.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN :—In a late issue of your valuable journal I read an article recording Dr. Schunn's experience in the use of potassium bromide in salivation. In an article of mine published in the *New Orleans Medical Journal*, I mention the use of this medicine in a case coming under treatment during the month of June, 1885, also stating that I had treated cases of like nature with it during several years.

I especially remember writing concerning a case of nursing sore mouth, complicated with excessive salivation, resisting treatment until I put her on this remedy, locally and internally. I was gratified in making a complete cure, and believe any case, neurotic or reflex,

will be benefited, and many cured, by its use. I have also found it as efficacious in relief of painful dentition as a certain much-vaunted French remedy, and much cheaper.

Yours truly,

A. PARKER CHAMPLIN.

BAY ST. LOUIS, MISS., February 24, 1887.

Notes and Queries.

INCOMPATIBLE PRESCRIPTIONS.

The following examples of untoward results following the combination of familiar prescriptions are given in the *Deutsch-Amerikanische Apotheker-Zeitung* for January 15, 1887, as original with Ch. T. P. Fennel in "The Principles of Pharmacy." While these incompatibilities may be well known, yet their repetition as a reminder will not be devoid of interest.

A common and dangerous action is that resulting from the mixture of alkaloids with alkalies or alkaline salts, of which the following is an example :

R Strichninae sulphat., gr. ss;
Elixir. brom. chloral., ℥viii. M.
Sig.—A teaspoonful morning and evening.

The result of this mixture is a colorless solution, from which is deposited in a few hours a crystalline precipitate, which is the greater portion of the strychnine ordered. Although the elixir is not officinal, it is frequently prescribed, and its potassium bromide will deposit the strychnine as an insoluble bromide. The last dose taken, unless great care to shake the mixture well was observed, would result disastrously.

The following prescription may also result badly :

R Morphin. sulphat., gr. ii;
Liq. ammon. acet., ℥ss;
Aqu. destillat.,
Syr. simpl., aa ℥ii. M.
Sig.—Teaspoonful doses as ordered.

When the diluted acetic acid has been neutralized, and an excess, although not great, of ammonium carbonate is present, the precipitation of the alkaloid will result as in the first instance.

The following may also prove incompatible :

R Potass. iodid., ℥i;
Spts. æther. nitros.,
Aque, aa ℥i. M.

When the spiritus ætheris nitrosi is not

free from nitric and acetic acids (a result which is produced by the action of the air) iodine will be set free, and a colored solution take the place of a colorless one. The chemistry of the decomposition of the spiritus ætheris nitrosi is as follows :

A familiar example of decomposition occurring in the organism when chemical substances are given is found in the simultaneous use of calomel and potassium iodide, as follows :

R Hydrarg. chlor. mit., gr. iv;
Sacchar. lactis, gr. x. M.
F. pulv. No. 10.

Sig.—A powder three times daily.

Also

R Potass. iodid., ℥i;
Aqu. destillat., ℥iv. M.

Sig.—Teaspoonful every three hours.

A reaction between the calomel and potassium iodide occurs in the stomach, and bad results, through the irritating mercurial formed, may occur.

An explosion or unfortunate formation of gas may result from this prescription :

R Ammon. carbonat., ℥ii;
Syrup. scillæ, ℥i;
Syrup. senegæ, ℥i. M.

The acetic acid in the syrup of squill has been overlooked in this combination: its union with the ammonium salt would result unfortunately through the liberation of carbonic acid gas.

In those cases where ingredients are ordered which even in a measure tend to produce insoluble compounds, the ingredients should be diluted as much as possible, that the resulting coagulum or compound may be easily dissipated by shaking. This is illustrated by the prescription—

R Liq. ferri chlorid., ℥iss;
Muc. gum. arab., ℥i;
Aqu. destillat., ℥iv.

in which the iron and mucilage should both be diluted before mixing.

The same caution obtains when tannin or liquoritia is combined with metallic or alkaloidal salts.

R Extr. hyoscyami aq., ℥ss;
Tinct. valerian., ℥iii;
Spir. ætheris nitrosi, ℥vi. M.

In the above the extract is to be diluted before mixing with the spiritus ætheris nitrosi.

The prescription

R Tinct. iodin., ℥i;
Aqua, ℥i. M.

will result in the separation of free iodine; to prevent this potassium iodide should be added.

The prescription

R Potass. chlorat., ℥i;
Acid. hydrochlor., ℥ii;
Aq. destillat., ℥x. M.

results in different ways. If the potassium chlorate is immediately added to the acid, and then water mingled with the resulting fluid, chlorine gas is formed in solution. If the potassium chlorate is first dissolved in water, and then the acid is added, free chloric acid results.

A NEW "CURE FOR CANCER."

DR. VELLOSO lays claim to having cured several cases of epithelioma of the face and lips with the juice of alvelos, a plant which belongs to the family of Euphorbiaceæ. It acted as an irritant, and destroyed the diseased tissue, which was quickly replaced by healthy granulations. Of the three different kinds of alvelos (male, female, and wild), the second is considered the most efficacious. It is found at Pernambuco, and although the natives have employed the juice for some time, it has not come into extensive use on account of the severe pain which it causes. The best results were obtained with the juice in a concentrated solid form, and with the addition of vaseline or lanoline. This preparation should be applied with a brush to the affected part (previously washed with a solution of carbolic acid), which should then be left exposed to the air for at least an hour. It should afterwards be covered with lint. This treatment should, as a rule, be repeated every two or three days, and never more than once in twenty-four hours, as the pain of the application is severe. The treatment was more speedily successful when begun before ulceration had occurred.—*British Medical Journal*, January 1, 1887.

ADONIS VERNALIS IN HEART-DISEASE.

DR. J. G. HERRMANN, of St. Louis, writes us that he has recently had considerable experience with the use of adonis vernalis in cardiac affections. He believes that his experience, which has extended over ten months,

warrants his statement that, while free from the evil effects of digitalis, infusions of *adonis vernalis* are quite as efficacious as that drug. He prescribes it in the form of an infusion, of the strength of three drachms of the herb to six ounces; of this he gives a tablespoonful every two hours. He refers to several cases in which this drug proved successful even after digitalis had failed. One was a case in which the feet were highly œdematous, and there was general anasarca from heart-lesion. In two weeks of treatment with the infusion of *adonis vernalis* every two hours, in tablespoonful doses, almost perfect relief was secured. So also he states that he has caused great relief to a case of ascites, produced through heart-disease. He noticed that it increased the fulness of the pulse and strengthened the cardiac pulsation. In asthma also he has combined it with *quebracho* with very satisfactory results.

The following are some of the prescriptions which he has employed :

R Fl. ext. *adonis vernalis*.
Sig.—From 2 to 6 drops, as necessary.

R Fl. ext. *adon. vernal.*, ℥ss;
Syr. menth. pip., ℥vi.

Combined as desired sometimes with brom. sodium and tr. *opii camph.*

Sig.—℥i every two hours daily.

In asthma :

R Fl. ext. *adonis vernalis*, ℥ss;
Fl. ext. *quebracho*, ℥ii;
Tr. *opii camph.*, ℥ii;
Syr. menth. pip., ℥vi. M.
Sig.—℥i every two hours.

HYSTEROGENIC ZONES ON THE MUCOUS MEMBRANES OF HYSTERICAL SUBJECTS.

DR. L. LICHTWITZ, of Bordeaux, following up the researches of Gaube on hysterogenic zones on the external surface, and of Blau-Fontenille on lethargogenic and lethargoinhibitory zones in hysterical subjects, has shown that not only the external, but also the mucous, surfaces of the body present in certain hysterical subjects areas the touching of which induces attacks either of a convulsive or a hypnotic character. This may be important in case examination with the nasal speculum, the laryngoscope, or other instruments is required. In some cases it was found that even cocaine did not prevent an attack. Dr. Lichtwitz points out the importance of knowing the spots where inhibition

or arrest of convulsions can be produced, in case of the accidental induction of an attack. According to his observations, there is no accessible part of the mucous membrane which may not be the seat of "hysterogenic zones," the most usual place being the nares. In one of his cases, one side of the nostril evinced spasmogenic and the other lethargogenic properties.—*British Medical Journal*, February 12, 1887.

STOMACH DIGESTION.

Opportunities for studying gastric digestion through fistulous openings into the stomach are, thanks to modern surgery, more frequent than formerly. This is important, as the physiology of digestion, as understood at the present day, requires more than the classical instance of Alexis St. Martin to place it on a sound experimental basis. Such a case with experiments *ad hoc* is recorded in the *Revue Scientifique* by VON HERZEN, of Lausanne. The subject was a man, æt. 28, on whom gastrostomy had been performed for occlusion of the œsophagus. The observations made were as follows : Bile always appears in the stomach during digestion, but generally only in the later stages. The amount of HCl amounts to 1.8 to 1.9 grm. pro litre; it increases during digestion and reaches its maximum in the third hour. Sodium chloride appears rather to diminish the amount of acid. When the stomach was empty in the morning but little pepsin was found, and a large amount of propepsin; peptogen accelerated digestion. In the first hour, of a quantity of albumen introduced, two per cent. was digested without peptogen, twelve per cent. with it. In the second hour, twenty-three per cent. was digested without, forty-five per cent. with peptogen. In the third hour, fifty-one per cent. without, seventy-six per cent. with, peptogen. These results agree with those obtained by Schiff. Chloral, quinine sulphate, and above all potassic iodide, retard digestion. The author would forbid red wine in disturbances of digestion, but would recommend bouillon and dextrin; blood fibrin is also indicated in many cases.—*Medical Press*, January 12, 1887.

THE CURE OF HYDROCELE BY CORROSIVE SUBLIMATE.

MR. JAMES MILLER in a recent number of the *Lancet* recommends the following method in the treatment of hydrocele : The contents

of the sac are to be evacuated, and $\frac{1}{2}$ of a grain of corrosive sublimate dissolved in 15 minims of water (the solution therefore being one grain to the ounce) injected into the sac. This treatment Mr. Miller claims will cause no pain and no return of effusion. The author states that he has employed this method in four cases in which simple tapping had been previously several times followed by the return of the effusion, but that permanent cure resulted after the employment of corrosive sublimate injections.

TREATMENT OF CEREBRAL PNEUMONIA.

HUCHARD advises the following regimen in the case of a child 16 months old :

1. Emetics.
2. Counter-irritants used for three hours at a time.
3. Brandy, in doses of $2\frac{1}{2}$ drachms.
4. Per rectum,

Aquæ, ℥iiss;
Quininæ bisulphat., gr. iiss.

And later in the disease the following :

Aquæ destill., ℥x;
Valerian. pulv.,
Sodii bromid., aa gr. v;
Camphor,
Muscæ, aa gr. iii;
Mucilag. acaciæ, q.s.

THE DIGESTION OF MILK.

M. REICHMANN, of Warsaw, has recently made several experiments on the digestion of milk in the human stomach. The subject was a young man, aged 22, in robust health. The experiments were made by means of the stomach-pump, with unboiled, as well as alkaline and boiled milk. The results were as follows: Three hundred cubic centimetres of unboiled milk are evacuated by a healthy stomach four hours from the time it has been taken, although the regular digestion is completed three hours afterwards. Coagulation of the milk takes place about five minutes after ingestion, and does not depend on increase in the quantity of acid, but on another agency, possibly the fermentation of rennet. During the digestion of three hundred cubic centimetres of milk, the contents of the stomach show the greatest average degree of acidity (thirty-two centimetres per cent.) at the end of an hour and a half. This acidity is owing, when digestion begins, to the presence

of lactic and hydrochloric acid; the latter only appears three-quarters of an hour after the ingestion of milk. Half an hour after taking the milk, the quantity of peptones is increased, and remains so for an hour and a half, after which time it becomes perceptibly less. Boiled milk (heated at from 16° to 26° C.) was taken into the stomach; three hundred cubic centimetres were digested in two hours and a half; the acid contents of the stomach disappeared in three hours. After the ingestion of boiled milk, peptonization, which in that case is more energetic, begins sooner, and the clots and caseine are not so thick as when unboiled milk is given. Experiments with alkalized milk have shown that alkalization of milk prevents the peptonizing action of gastric juice. One hundred cubic centimetres of milk, alkalized by means of bicarbonate of sodium, leave the stomach entirely at the end of two hours. Alkalization does not prevent milk in the stomach from coagulating under the influence of rennet. In conclusion, M. Reichmann says that the result of all his experiments on one person entirely coincided with nine previous experiments he had made.—*The British Medical Journal*, February 12, 1887.

TO STOP TOOTHACHE.

GESELL-FELS makes the following mixture, which is an oily liquid, and introduced in the tooth cavity has proved very effective :

Camphor, gr. lxxv;
Chloral hydrati, gr. lxxv;
Cocaini muriat., gr. xv.

PRESCRIPTION FOR HEADACHE.

The following is from DUJARDIN-BEAUMETZ :

Ethoxycaine, gr. xii;
Sodii salicylat., gr. xv;
Aquæ destill., ad ℥i.

Dose.—Teaspoonful or table-spoonful.

GUIBAUT recommends the following in psoriasis :

Sodii arsen., gr. $\frac{1}{4}$;
Ext. gentian., gr. iss.

In pill form.—Two or three pills after each meal.

Also frictions twice daily with

Adipis, ℥iii;

Acid. pyrogall., ℥iiss to ℥iv.

Also a thorough cleansing with soap every two days.

THE TREATMENT OF PHTHISIS BY SULPHURETTED HYDROGEN.*

By H. C. Wood, M.D.

IT has not been many years since the faces of patients in a consumptive hospital were merged into a uniform ugliness, each in fact being cased in a mask of greater or less proportion, with various machinery in its centre, which was dignified by the name of a respir-

ator. It is noteworthy that the respirator was armed with germicides or antiseptics, and was to cure consumption antiseptically. Now the destroyer of phthisis germs and the characteristic phenomenon of the pulmonary hospital bids fair to be a caoutchouc bag, a bottle of bad-smelling solution, and a rectal tube and nozzle. Whether this last claimant for therapeutic favor shall, as is not improbable, finally follow the respirator into oblivion or not, is at present uncertain. But the matter certainly is of sufficient importance to require careful treatment at the hands of the THERAPEUTIC GAZETTE.

In 1883, M. Debove, professor at the *Hôpital de la Pitié*, declared in one of his clinical lectures that consumption being due to

* Dr. V. Morel, "Nouveau Traitement des Affections des Voies Respiratoires." Paris, 1886. *Gazette Hebdomadaire*, December 17, 1886. *La Semaine Médicale*, July 14, 1886; October, 1886.

the presence of a parasite, the proper treatment of it was the use of a parasiticide. It was left, however, for M. Bergeon (of L'Ecole de Médecine of Lyons) to put into actual practice this suggestion, and on the 12th of July, 1886, he gave his results to the French Academy of Science. He rejected the lungs themselves as the channel through which the parasiticide should find entrance into the system on account of the rapidity of absorption from them, and of the fact that medicines taken up by them are carried immediately in a concentrated form to the right side of the heart, and, moreover, exert in the lung itself a too great local irritant influence. The disagreeable tastes of most of the antiseptics render their administration through the mouth and stomach difficult, whilst the work of Claude Bernard has shown that gaseous substances taken into the large intestine are absorbed with great rapidity and go into the general system. M. Bergeon, led by this train of thought, used various substances, such as chlorine, turpentine, ether, ammonia, and bromine injected into the rectum, but found them all so violently irritating that they had to be abandoned, but at last he discovered that a mixture of carbonic acid and sulphuretted hydrogen was perfectly tolerated by the intestines, if the gases be pure and be unmixed with atmospheric air. Under these circumstances the rôle of the carbonic acid was to act as a diluent to the sulphuretted hydrogen.

The apparatus of M. Bergeon consisted of a caoutchouc bag having a capacity of four or five litres, which was filled with pure carbonic acid and connected with a Wolffe's bottle, which was in turn connected with the tube inserted into the rectum of the patient, so that by compressing the bag the carbonic acid could be forced to bubble through the solution of sulphuretted hydrogen, natural or artificial, in the Wolffe's bottle, and pass into the intestines. The common sulphurous waters, especially Eau de Bonnes or Eau de Challes, were thought by Bergeon to be superior to any artificial waters, but this is probably a mistake.

In the Hôpital Cochin, where the method has been much practised, the following two solutions have been employed :

SOLUTION NO. 1.

R Sulphide of sodium, pure, 10 grammes, or 10 parts by weight;
Distilled water, enough to make 100 cubic centimetres, or 100 parts by weight.

One cubic centimetre of this liquid engages exactly ten cubic centimetres of sulphuretted

hydrogen when there is added to it one cubic centimetre of the following solution (No. 2) :

SOLUTION NO. 2.

R Acid, tartaric, 25 grammes, or 25 parts by weight;
Acid, salicylic, 1 gramme, or 1 part by weight;
Distilled water, enough to make 100 cubic centimetres, or 100 parts by weight.

This solution in the Hôpital Cochin is used by an apparatus which, under the directions of Dujardin-Beaumetz, is made by H. Gallante, of Paris, and which, though much more complicated, is no doubt more convenient than the apparatus of Bergeon. A description of this apparatus with figure may be found in *Les Nouveaux Remèdes*, November 24, 1886.

By M. Bergeon himself four or five litres of carbonic acid gas, which had been passed through two hundred and fifty to three hundred grammes of the sulphurous mineral water, were thrown into the rectum twice in each twenty-four hours. In the Hôpital Cochin the amount of gas injected varies from one to four litres at each séance. The apparatus used at this hospital is superior to that used in the original method, because it allows a definite amount of sulphuretted hydrogen to be introduced with the gas. The amount of sulphuretted hydrogen used in the Hôpital Cochin is not positively stated, but about fifteen cubic centimetres of the solution of sulphide of sodium (equivalent to one hundred and fifty cubic centimetres of sulphuretted hydrogen) seems to be the amount employed at a séance.

In his original communication, M. Bergeon claimed that the success of this mode of treatment is very rapid and remarkable ; it is stated that the cough immediately diminishes, the expectoration lessens or even ceases, the appetite increases, the sleep becomes undisturbed, the fever abates, and the bodily weight greatly increases.

In the discussion before the Société de Thérapeutique, at the meeting of December 8, 1886, Dujardin-Beaumetz confirmed the statements of M. Bergeon, and further said that the amelioration must be due to the sulphuretted hydrogen, as he had repeatedly tried injections of pure carbonic acid without doing good.

The French reports indicate very strongly that the drug acts, not as was originally expected, upon the parasite of phthisis, but upon the inflamed diseased lung-tissue itself, since Dujardin-Beaumetz states that there is no lessening in the number of bacilli in the sputa : moreover, great benefit is obtained in the treatment of cases of simple chronic

bronchial catarrh. This is also confirmed by the studies of M. Chentemesse, of the Hôpital St. Antoine, who affirms distinctly that there is no lessening of the bacilli, and that very marked relief has been afforded to asthmatic patients. Moreover, *no evidence is forthcoming to show that sulphuretted hydrogen is poisonous to the tubercular bacillus*. It is, so to speak, the natural gas of putrefaction, and without definite proof cannot be considered to be even probably inimical to low organic forms.

Dr. James Henry Bemett has published in the *British Medical Journal*, December, 1886, a paper upon Bergeon's method of treatment, in which, however, he adds nothing to our knowledge of the subject, merely stating his own experience in a single case of asthma.

In this city the method of treatment has been used in the Philadelphia Hospital in a large number of cases, especially in the wards of Dr. Bruen. A personal inspection of the result shows that the statements made by the French observers are correct, and there seems to be no doubt that under the treatment there is rapid alteration of some cases of phthisis for the better. In the Philadelphia Hospital the solution at first used contained five grains of the chloride of sodium and five grains of the sulphide of sodium, but at present the strength has been doubled, so that in the Wolffe's bottle, through which the carbonic acid passes, ten grains of each of the chemicals is put. Once charging of the Wolffe's bottle is made to suffice for a number of patients, each of whom receives at each treatment from three to five pints of carbonic acid. It will be seen at once that in this method the amount of sulphuretted hydrogen received by the patient is unknown and variable, and is very small. A personal inspection of the carbonic acid used showed that it is very impure, the odor indicating that it contains sulphurous acid. Chemical testing has shown that the gas coming from the Wolffe's bottle contains sulphuretted hydrogen, the odor of which is also distinctly present. The chloride of sodium in the solution would appear to be superfluous, the carbonic acid reacting directly with the sulphide of sodium. The following formula represents the probable change: $\text{NaS} + \text{CO}_2 + \text{H}_2\text{O} = \text{NaCO}_3 + \text{H}_2\text{S}$.

Such is the evidence which I have been able to gather from the experience of others in regard to Bergeon's treatment, and it is sufficient to indicate that we are in the presence of a very important improvement of, or rather a very important addition to, medical therapeu-

tics. It is of vital importance to decide the mode in which the treatment acts. The experiments of Dujardin-Beaumetz show that the carbonic acid is not the active agent, and that the good achieved is produced by the sulphuretted hydrogen. Reasons already assigned are sufficient to make it improbable that the good achieved is the result of any parasiticial influence. All clinical experience indicates that heredity is in the production of consumption a vastly more important factor than is any poison introduced into the body from without. Only a portion of the medical profession believes in the active contagiousness of phthisis, whilst the experience of any life insurance company affords a firm foundation for the belief in the heredity of the disease. If the bacilli really are the exciting cause of phthisis, the susceptibility to their action must be a more important factor in the production of phthisis than are the bacilli themselves. There is at present, then, no proof that the sulphuretted hydrogen, when it does good in phthisis, acts by killing the bacilli, and there is still less proof that it in any way increases the direct resistive powers of the individual to the action of the bacilli. In some acute and chronic diseases of the skin, local applications of sulphur act with the most astonishing rapidity and effectiveness, and the thought naturally suggests itself that in Bergeon's treatment of consumption good is achieved by the action of the sulphuretted hydrogen upon the inflamed lung-tissue, or in other words, that the plan of treatment is simply a means of making an application of sulphur to the pulmonic mucous membrane and tissue. This thought is not merely of speculative interest, but also of practical importance, for it suggests that the method of treatment will prove of value not only in consumption but in various forms of chronic or subacute affections of the lungs. This is confirmed by what experience we have. Cases of asthma and pulmonic catarrhs have already been quoted in this article as having been published in the French journals, in which the remedy has proven of the greatest service.

I saw in the Philadelphia Hospital one case of asthma with chronic catarrh and emphysema in which the administration of the rectal injections had been followed by the most pronounced relief. In another case, of catarrhal pneumonia with an enormous amount of purulent expectoration, and general symptoms so bad that a fatal prognosis had been given, the administration of the remedy was at once

followed by rapid lessening and even cessation in the purulent secretion, and in a short time by convalescence.

As an important illustrative case, I cite one from my own recent experience. Mrs. L., over 70 years of age, received a severe contusion of the side in a railway accident, which was followed by pleurisy, in turn followed by bronchial pneumonia, with an enormous expectoration. She has been under my care for nearly three months, and though often temporarily benefited by various remedies, had failed to properly respond to the most careful treatment that I could give her. The expectoration remained exceedingly profuse, amounting sometimes to a pint in the course of twenty-four hours, although very irregular. The general symptoms were very bad: sinking spells were frequent and alarming. I finally told the family that she would die, unless the gaseous injections would do something for her. Within forty-eight hours after the use of the gas, the expectoration notably decreased; the expression of the patient's face changed entirely, and at present writing, fifteen days after the use of the sulphuretted hydrogen, she is expectorating not one-sixth the quantity she did formerly, has regained the natural expression of her face and color of her skin, as well as her appetite, and a fair amount of strength, and seems to be convalescent. A notable fact in this case is that the injections of gas relieve in a few minutes the sense of suffocation and sinking the patient formerly felt in the mornings. The secretion of urine was sensibly increased. As tested on three occasions, the subnormal temperature rose 0.4° F. within the half-hour after the exhibition of the gas either by the mouth or rectum.

One difficulty with Bergeon's method of treatment in private practice is the cumbersome apparatus and the skilled labor required for the preparation of the carbonic acid. A plan which would avoid this and reach the same result in regard to the lung-disease is certainly a desideratum.

According to Gay-Lussac and Thénard, water at 52° Fahrenheit will absorb three times its volume of sulphuretted hydrogen. To prepare this solution, the gas, previously washed with water, is passed alternately through each of two bottles half filled with water; while it is being passed through one, the other is closed with the stopper and shaken, to insure complete absorption; and thus the process is continued till the water is completely saturated. One of the bottles is then completely filled with the liquid, and re-

moved with the mouth downwards. The resulting solution is a colorless liquid, having the odor of putrid eggs, and a sweetish taste. When heated, it evolves the whole of the gas. Bottles containing the solution of sulphuretted hydrogen should be habitually laid upon their side.

A priori, there is no evident reason why this solution, if injected into the rectum in proper doses, should not exert all the influence upon the pulmonic tissue obtained by Bergeon's treatment. I have tried the solution thrown into the rectum, and found it free from any irritant action. The habitual use of injections two or three times a day is, however, very disagreeable to most patients, and the questions naturally arise, Is there any necessity of administering the drug by the bowels, and will not sulphuretted hydrogen water be taken without too much repugnance by the mouth and without nauseating? At the various sulphur springs large quantities of such water are habitually drunk by the patients. Led by such considerations, I have tried the sulphuretted hydrogen water in as many cases as I have been able to get, and so far, when properly given, it has been usually taken readily, and has not disagreed with the stomach. Some persons, however, will not tolerate it at all. The effects upon the disease have seemed to be entirely similar to those produced by the injections. At first a half-ounce, afterwards an ounce, of the saturated solution of the sulphuretted hydrogen should be placed in a tumbler, and two or three ounces of carbonic acid water be run into it from a highly-charged siphon, the whole being drunk while effervescing. This may be given three to five times a day, so that the patient will receive daily between a half-pint and a pint of the sulphuretted hydrogen gas. Injections of gas into the rectum produce in some persons more or less violent attacks of colic, especially if given at a time when the food is well down in the intestinal tract. Thus, in the case of Mrs. L. the night injection caused so much pain that it could not be borne, although the injection in the morning was actually pleasant. The two methods of administration were then combined, the gas injection being given in the morning and the sulphuretted hydrogen water in the afternoon and evening. Within the last forty-eight hours, at Mrs. L.'s earnest request, the gas injections have been entirely abandoned in favor of the exhibition by the mouth. Of course the two methods are simply different ways of accomplishing the same result, and

may be variously combined or substituted for one or another according to the peculiarities of the individual cases within the last day or two.

It is a matter of the greatest importance to fix definitely the dose of sulphuretted hydrogen gas. With the method employed in the Philadelphia Hospital this cannot possibly be done. The solution employed in the Hôpital Cochin, whose formula is given in the first part of this article, seems to be superior to the solution of the chloride and the sulphide of sodium, in affording known quantities of sulphuretted hydrogen. Even with it, however, the chemical reactions are so slow that practically it is scarcely possible to decide how much of the gas is evolved in a brief time. The substitution of sulphuric for tartaric acid would largely obviate this. When the medicine is given by the mouth exact dosage is possible. In Mrs. L. five ounce-doses appeared to be too much. She is now taking three doses daily.

In a recent number of the *British Medical Journal* it is stated that M. Morel affirmed before the Biological Society of Paris that the dose of the gas is twenty-five cubic centimetres. That it is not incapable of doing harm is shown by the experiments of M. Peyron, who injected into the rectum of a dog one hundred and fifty cubic centimetres of a saturated solution of sulphuretted hydrogen in two doses at intervals of three minutes. Symptoms of poisoning began to be manifested within two minutes, and death took place in ten minutes. Another dog died quickly after two injections of the same strength, given at intervals of twelve minutes, while two others, in whom only very small quantities of the gas, or large quantities very much diluted, had been injected, experienced only slight inconvenience, and rapidly recovered. Not long since, in the University Hospital in Philadelphia, about one quart of a mixture containing equal quantities of carbonic acid and sulphuretted hydrogen were injected into the rectum of a patient; within three minutes the man was unconscious and apparently dying. The breathing-rate was one hundred per minute, and the respirations so shallow that they could scarcely be observed. The pulse at once became very rapid and feeble, and even imperceptible at the wrist, while a very marked odor of sulphuretted hydrogen appeared in the breath. Under treatment the symptoms all subsided in about fifteen minutes. The rapidity with which these symptoms developed and with which they subsided indicates that when the gas is thrown into the rectum

its effect is very immediate and fugacious, and it is entirely possible that the more continuous influence of rectal injections of the aqueous solution of sulphuretted hydrogen may act better in pulmonic diseases than does the short influence of the gases now administered. Of course poisoning by overdoses of sulphuretted hydrogen is a no more valid objection to its proper use than is opium poisoning to the employment of opium.

CUNEIFORM OSTEOTOMY FOR ANTERIOR CURVATURE OF BOTH TIBIÆ AND BOTH FIBULÆ.*

BY MILTON JOSIAH ROBERTS, M.D.†

(Concluded from page 163.)

CLINIC OF OCTOBER 26.

I THOUGHT it might be of interest to you to bring before you to-day the little colored boy upon whom we operated a week ago for the correction of anterior tibial and fibular curvatures. It is always well to know the history of a case subsequent to an operation in order to correctly judge of the value of the operation. An operation may at the time of its performance appear to be a very brilliant one, but in the light of subsequent events may take on an entirely different appearance. You will remember that we performed four cuneiform osteotomies upon this patient, requiring eight complete divisions of the bones of the leg. Fortunately for us, Dr. McNutt was able to provide a bed in the babies' ward for our patient, so that his subsequent condition could be carefully watched. Dr. Vinton, who has had charge of the patient since the operation, reports his condition as follows: October 19, after the operation, at 4.45 P.M., his temperature was $98\frac{3}{8}^{\circ}$, pulse 89, respiration 30. On October 20, at 4 P.M., his temperature reached 101° , but quickly began to fall. On the 22d inst., the third day after the operation, his temperature fell to normal, and has remained so ever since. There is no indication of any suppuration, the dressings re-

* A Clinical Lecture delivered at the New York Post-Graduate Medical School and Hospital, October 26 and December 18, 1886.

† Professor of Orthopædic Surgery and Mechanical Therapeutics, Visiting Orthopædic Surgeon to the City Hospital on Randall's Island, Consulting Orthopædic Surgeon to the Woman's Hospital, Brooklyn, etc. Phonographically reported by J. J. Sullivan, M.D.

maintaining perfectly dry and clean. He is now eating and sleeping well, and all his bodily functions seem to be normally performed. We will endeavor to keep this patient under observation, that you may note for yourselves the progress of the case.

Now, with regard to the correction of anterior tibial curves. I know you will hear a great many physicians say it is a perfectly simple matter to overcome these deformities by means of operations performed with the chisel and mallet. I have yet to see, however, the report of any cases in which the

the jars which are communicated to the bony framework by means of the repeated blows of the mallet upon the chisel are transmitted to the central nervous system, and necessarily are the cause of more or less shock. I have known of more than one patient operated upon for tibial curvature with the chisel and mallet who has lost his life in consequence of the operation, and who, at the time of the operation, was in perfect health. Such disastrous results, however, are not as likely to find their way into medical literature as those of a more pleasing nature.

FIG. 1.

Showing result of operation.

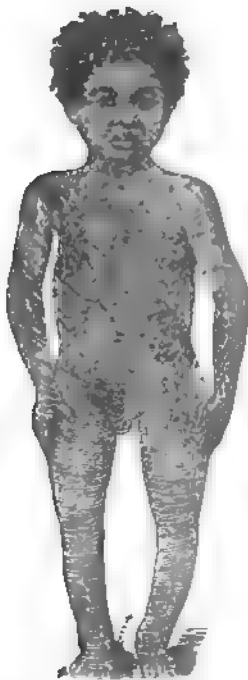

deformity was so exaggerated as in this case where it has been completely rectified. You can readily appreciate this when you recall to mind the difficulties which the surgeon must necessarily encounter when he endeavors to remove a wedge-shaped piece from a bone by means of a chisel. At best it can only be accomplished in a bungling and unworkmanlike manner, for a chisel is not the tool with which to remove V-shaped pieces from any hard substance. In any of the mechanic arts a workman desiring to remove a V-shaped piece from any hard substance would never think of resorting to the use of a chisel. Then, again,

CLINIC DECEMBER 18, 1886.

I have again brought before you the little colored boy upon whom I operated about eight weeks ago, this time with the dressings removed. He has not had an untoward symptom since the operation, and union of the bones and soft parts has taken place without the formation of pus. As you see, when placed in the position in which he was originally photographed, the anterior deformity has been perfectly corrected. (See Fig. 1.) You will remember on the occasion of the operation I directed your attention to the fact that this child presented a double deformity, viz.,

anterior curvature of both tibiae and both fibulae, in conjunction with a slight degree of bow-leg deformity. These deformities, the anterior and the lateral, it should be borne in mind, lie in two different planes. In the anterior deformity the right and left plane of the leg is distorted, while in the bow-leg deformity the mesial plane of the leg is distorted.* The anterior deformity of the leg-bones has been perfectly corrected. No attempt, however, was made to correct the bow-leg deformity at the time of the operation. When placed upon his feet (see Fig. 2) you will

FIG. 2.

Showing bow-leg deformity.

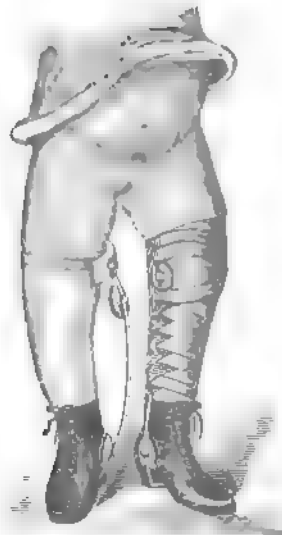

readily appreciate the persistence of this deformity. And it is to a practical point connected with the correction of deformities lying in two planes to which I wish now to direct your attention.

Had I deemed it perfectly safe to have divided the bones of the tibiae and fibulae just distal to their proximal epiphyses, on the occasion of the operation for the correction of the anterior deformity, I could have readily corrected the bow-leg deformity, and he would now have been presented to you with perfectly straight legs. It has not, however, been shown, so far as I am aware, that it is perfectly safe to endeavor to straighten at one sitting a bone which is deformed in more than one plane. The thought which has al-

ways deterred me from the multiple cross division of long bones has been the fear of interfering with their nutrition. I am not at all satisfied, however, that it is not feasible to undertake such an operation, but until I have knowledge of its reliability from other sources, I shall not hazard such a procedure upon a living human being. It would be of great practical value to perform a series of experiments upon the lower animals in order to determine the limitations to multiple cross-sections of the long bones. If it can be demonstrated, as a result of these experiments, that we can make a complete section of a long bone in two or more planes without interfering with its nutrition, nothing will be simpler than the straightening of long bones that are deformed in more than one plane. Experiments on living human beings should never be undertaken unless they are legitimate, and experiments only become legitimate when, by means of a rational line of thought, observation, or experimentation, the conclusion is reached that they are feasible. Thus reinforced, we feel confident of the justice of our undertaking, and experimentation then takes on the garb of legitimacy.

What I propose to do in this case, however,

FIG. 3.

Bruce's bow-leg apparatus.

is not now to submit the patient to a second operation for the correction of his bow-leg deformity, but to correct this by mechanical means. For this purpose I shall make use of an extremely simple form of apparatus, the invention of Dr. Charles E. Bruce, one of the assistants to the orthopaedic chair in this in-

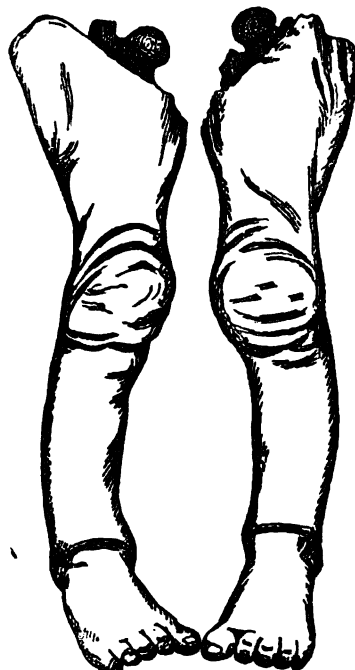

* Anatomical Geometry and Toponomy, etc.

stitution. This apparatus consists (as will be seen by reference to Fig. 3, right lower extremity) of three pieces, with joints corresponding to the ankle and knee, and is placed upon the inner aspect of the limb. It is made of very light pieces of steel. The first segment of the instrument extends from the sole of the shoe to the ankle-joint, and is riveted directly to the sole of the shoe in front of the heel. The second segment of the instrument is a narrow strip of stiff steel, having a curvature, which approximates in degree that of the deformity to be corrected, only that it is in the opposite direction. The third segment extends a short distance above the joint. It is provided with a curved piece, riveted at right angles to the shaft of the instrument, this curved piece serving to keep the upper part of the instrument in position on the limb. Now a roller-bandage is carried about the limb and over the instrument, the latter being drawn up close to the limb, as shown for the left lower extremity, Fig. 3. Instead of using a roller-bandage to secure the apparatus in position, I prefer to draw on an elastic cap, which extends from a little above the ankle-joint to a point just below the knee-joint. By the use of an elastic cap of this kind much time is saved in applying and removing the apparatus. It is also not so apt as the roller-bandage to get out of position. The curved shaft of the instrument being made of spring steel, and tempered, when straightened out and drawn close to the limb gently tends to return to its former curved form. The pads attached to the instrument opposite the ankle- and knee-joint serve as points of counter-pressure, and tend to straighten the limb. This apparatus should be worn day and night, but it should be removed each day, not only for the purpose of cleanliness, but in order to manipulate the muscles, as the prolonged wearing of bandages, even though the patient exercises considerably, is likely to cause more or less muscular atrophy.

The appropriateness of the idea of applying force in one direction to the shafts of the tibia and fibula, and a counterforce in the other direction to the epiphyses of these bones, as is accomplished by Dr. Bruce's instrument, will be understood when we come to consider the anatomical relationships of the parts involved in bow-leg deformities. Two or three years ago I made some dissections of the limbs of the lower extremities of very young children, which convinced me that in these deformities we must at least not always expect to find the shafts of the tibia

and fibula curved outward. Fig. 4 represents the dismembered lower extremities of a

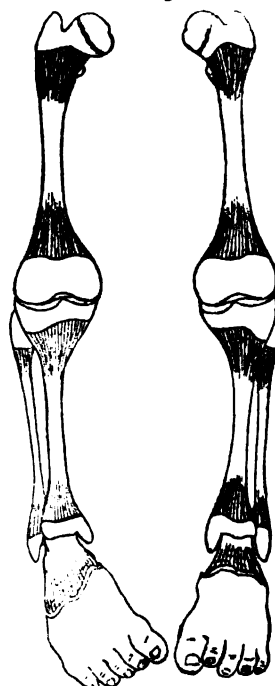

FIG. 4.

Lower extremities dismembered.

child one month old. From an inspection of this figure it would appear that the tibial

FIG. 5.

Same, denuded.

shafts were curved outward. This impression is dispelled, however, when we come to re-

move the flesh from the bones. Fig. 5 represents the bones of the lower extremities, represented in Fig. 4, freed of their soft parts. From an examination of this figure it will be seen that the shafts of the tibiæ and fibulæ are straight. It would appear, therefore, that the deformity was due to a tilting of the epiphyses upon their diaphyses, or to some alteration in the epiphyses.

105 MADISON AVENUE, NEW YORK.

*CLINICAL AND PHYSIOLOGICAL NOTES
ON THE ACTION OF CANNABIS
INDICA.*

BY HOBART AMORY HARE, M.D.*

CANNABIS INDICA has been before the profession for many years as a remedy to be used in combating almost all forms of pain, yet, owing to the variations found to exist as to its activity, it has not received the confidence which I think it now deserves. At present certain improvements made in the method of obtaining the extract from the crude drug have very materially increased its reliability, so that by selecting an article made by a responsible firm we may be fairly sure of receiving a preparation in which we can place confidence. Within a few years this drug has become particularly prominent in connection with its use in migraine, particularly when used in conjunction with gelsemium, although of the two remedies the hemp is by far the most active agent in subduing the pain and preventing other attacks.

Heretofore the profession has used the remedy in such cases purely from an empirical stand-point, but I shall in a moment explain more fully its true physiological action. Aside from this, however, I have certainly seen very severe and intractable cases of migraine successfully treated by this remedy, not only in regard to the attack itself, but by acting as a prophylactic. The best use of the remedy under such circumstances is as follows, in case the drug obtained be fairly active. If the attacks are frequent then the remedy should be used constantly in small doses, in such a way that the patient is not conscious of any influence of the drug, and about $\frac{1}{8}$ of a grain of the solid extract may be taken night and morning, or, if this produces any tendency to sleep, the whole amount may be taken at night. At

the beginning and during the attack it should be freely administered, until either the pain is diminished or very marked symptoms of its physiological action assert themselves; and that this line of treatment is not one calculated to produce serious results is proved by my own experiments, and by the fact that so far no case of fatal poisoning from its ingestion has been recorded as occurring in the human being.

I myself have taken as much as one grain of the solid extract of a very active preparation without producing any disagreeable symptoms other than that of a deep sleep, which lasted for nearly eighteen hours, preceded by a period of great hilarity, which did not pass into any sensation of dread, such as has been described by some persons.

When gelsemium is used in addition to the hemp, its usefulness is limited only to its action in warding off an immediately impending attack, and I do not believe it possesses much power for good unless it be given when the first symptoms of the malady appear. Its exceedingly poisonous properties necessarily prohibit any repetition of a dose, and for this and the reasons above stated the drug should be administered in one single dose of 15 to 20 drops of the tincture at the first sign of an attack.

Cases of migraine treated in this way, when the disease does not depend on any distinct organic lesion, are in a large proportion of instances either entirely cured or greatly benefited, the attacks even when they recur being considerably farther apart.

In neuralgias depending on a condition of debility in nursing women and in overworked men cannabis indica alone acts very favorably, not by acting in any way as a stimulant to the system, but rather by allaying any irritability of the nerve-trunks. Again, in many cases of irritative cough, depending either upon some nervous irritability or upon some actual irritated condition of the air-passages, cannabis indica will be of service in allaying the troublesome symptom, and is often found useful in the chronic winter cough of old people, provided no great outpouring of mucus or liquid is in the lungs.

In certain stages of phthisis it is a very valuable remedy, not on account of any influence possessed by it on the pathological processes, but by quieting restlessness and anxiety, and by turning the mind of the patient to other channels. Indeed, in cases of advanced phthisis I believe it would be justifiable to push the drug almost to the condition

* Demonstrator of Experimental Therapeutics and Instructor in Physical Diagnosis in the University of Pennsylvania.

known as euthanasia, and this has been done quite frequently by many practitioners. Under these circumstances, the patient, whose most painful symptom has been mental trepidation, may become more happy or even hilarious.

The advantages in its use over that of opium consist chiefly in the absence of prostration and nausea after its ingestion, and in the partial lack of soporific power which it possesses as compared to the opiate, for in certain cases sleep is not always desirable when pain is to be removed. That cannabis indica has, however, marked powers as a soporific is not to be denied. Added to these advantages is the fact of its failure to produce serious symptoms even if very large doses be taken, although I have found the efficient dose of a pure extract of hemp to be as powerful in relieving pain as the corresponding dose of the same preparation of opium.

That it is capable of producing a habit there can be no doubt, although whether its devotees are as devoted as are those of opium I cannot say. In my own practice I have seen a case of a young man who took his first dose as an experiment, and who afterwards had such a constant desire for its repeated use that he was forced to abstain from it entirely. He also said he could readily understand how the drug might have devotees, and that the pleasurable sensations excited were far preferable to those of alcohol.

During the time that this remarkable drug is relieving pain a very curious psychical condition sometimes manifests itself; namely, that the diminution of the pain seems to be due to its fading away in the distance, so that the pain becomes less and less, just as the pain in a delicate ear would grow less and less as a beaten drum was carried farther and farther out of the range of hearing.

This condition is probably associated with the other well-known symptom produced by the drug, namely, the prolongation of time.

Turning from the clinical stand-point of the drug to its physiological effects, we find that its clinical uses rest on a scientific basis, and I shall, therefore, detail one or two experiments showing in what manner the drug acts.

If a considerable quantity (mx)* of the fluid extract be given to a twenty-pound dog, by the jugular vein, in the course of two or three minutes he becomes very playful and happy,

* mviii of this preparation is the dose by the mouth for an adult man.

and gambols over the floor. In the course of about five minutes more there appears a slight stagger in the walk, which gradually increases, and is most marked in the fore legs, the condition of mental exhilaration continuing. Soon after this equilibration is partly lost, for the animal, sitting on its haunches, places its fore feet wide apart; nevertheless, in the course of ten minutes more he seems to partially recover his balancing powers, and to be as happy and frolicsome as ever, barking and running. In the course of twenty or twenty-five minutes more he vomits, and the swaying and staggering reassert themselves, now affecting both hind and front legs. This condition rapidly passes into a drowsy state, which, in turn, deepens into profound sleep, from which it is difficult to arouse the animal to consciousness, although the reflexes are markedly accentuated, particularly to sounds. This sleep lasts for many hours, and finally the dog wakes up himself again. In some instances a lack of co-ordination, due evidently to failure of sensation, appears, so that the animal places his feet on the floor as if it were uneven, or higher or lower than it is.

That the drug may be given in enormous amounts by the jugular vein in the dog without producing death is proved by the fact that I have injected as much as 10 c.c. of the fluid extract without producing serious symptoms. Thus, at 1.20 P.M. the injection was given. At 1.25 the dog was sound asleep and groaning, as if having bad dreams. At this time pinching the ear called out no sign of discomfort, and the respirations were eight per minute.

At 5 P.M. the animal was as sound asleep as before, but was unfortunately killed by the laboratory assistant, owing to a misunderstanding of my orders. Just before death the respirations had risen to ten per minute, and several movements had been made by the dog.

Again, I have given by the jugular vein 22 c.c. of a fluid extract, which I knew to be active, without producing death or any marked change in either arterial pressure or pulse-rate, as may be seen from the following condensed table:

DOG; ETHERIZED; WEIGHT, 40 POUNDS; FULL GROWN.

Time.	Drug.	Pressure.	Pulse.	Remarks.
3.01.10	114-144	186	
3.01.20	114-142	180

3.39.00	88-136	180	
3.41.10	126-156	174	
3.41.20	126-150	174	
3.41.37	7 c.c.	138-150	144	Injection begun.
3.41.42	136-154	138	Injection ended.
3.41.52	148-118	168	
3.42.02	90-140	150	
3.42.12	104-70	168	
3.42.22	98-68	156	
3.42.5	88-116	96	
3.44	118-92	102	
3.44.16	10 c.c.	98-124	105	Injection begun.
3.44.20	74-146	88	
3.44.40	54-34	96	
3.45	28-24	66	
3.45.10	26-22		Pulse imperceptible; heart stopped; respiration continued for ninety seconds after heart.

The only influence exercised on the circulation by the drug consists, as is seen by the above table, in a slight slowing of the pulse and fall of arterial pressure. That the slowing is due to direct cardiac depression and not to stimulation of the vagal centres is proved by the failure of the pulse to return to its normal rate when the vagi were cut. The fall in arterial pressure seems to depend entirely on the failure of cardiac power.

The 22 c.c. were given between 3.01 and 3.41, in four doses, ranging from 2 to 8 c.c. At 3.44 10 c.c. more of the extract was given rapidly into the jugular, producing death in about sixty seconds. In other words, it required 32 c.c. of the strong fluid extract, by the jugular vein, to produce death in a dog weighing forty pounds.

When we consider that this extract was active in doses of m^{viii} to man, it must be conceded that this drug has but slight lethal power.

Respiration continues after the heart ceases to beat in those cases in which the drug is sent into the cardiac apparatus *en masse* through the jugular vein; but when death is not due to this cause, there seems to be a simultaneous failure of heart-power and respiration.

The action of the drug on the nervous system is, of course, the most interesting part of the investigation, and we find that in the frog, as in the dog, the greater portion of its action is on the brain.

When a very large dose of the fluid extract (m^{v} to m^{xx}) is given hypodermically to the frog, it immediately becomes quiet, and in a moment or two will lie flat on its back, apparently in a deep sleep, with slow and full respirations. That the condition of relaxation is due to sleep or cerebral depression was proved by oft-repeated experiment, reflex action being increased very markedly, proving that the motor and sensory nerve-trunks were unaffected, as well as the motor and receptive centres in the cord. Reflex action, however, rapidly diminishes after remaining for five to ten minutes, and total relaxation comes on. That this is not due to motor-nerve or spinal palsy is proved by electric stimulation of the cord and nerve-trunks, which is always followed by contractions of the tributary muscles. The loss of reflex power, therefore, must depend on depression of the sensory apparatus, and further experiment confirms this reasoning, for, as was again and again proven, the drug, when applied locally to the exposed sciatic, invariably prevented the passage of the most powerful impulses from the foot to the cord. The poisoned foot could be burnt off without any response, while if the opposite leg was burned the batrachian instantly leaped away, using both the poisoned and unpoisoned leg, showing again that cannabis indica does not have much effect on the motor nerve-filaments even when directly applied to them. Under these latter circumstances, however, the poisoned leg is not moved quite as rapidly as its fellow, showing that the motor nerve has not escaped absolutely the direct application of the drug. That the sensory tract of the cord is affected was proved by tying the common iliac in order to protect the nerve-trunks of the posterior extremities, and then injecting the poison into the body. Under these circumstances there is, as usual, the first stage

of heightened reflex action, followed by corresponding depression of the same, and irritation of the protected sensory nerve fails to call forth any response from the spinal cord.

To summarize these conclusions, we find that cannabis indica produces in the lower animals a period of happiness followed by more or less deep sleep, according to the amount of the drug. That in both the dog and frog we have a stage of heightened reflex action following the dose.

That this increased reflex action is replaced by reflex palsy which is not due to motor-nerve or motor-spinal-tract palsy, but to failure of the sensory side of the cord and nerve-trunks.

That the chief action of the drug is upon the centres in the cerebrum, that the action on the sensory tract of the spinal cord and nerve-trunks is secondary to its cerebral action.

Before closing this paper I desire to call the attention of practitioners to the local anæsthetic action of this curious substance. As already detailed, when applied directly to the nerve-trunks it paralyzes them, and I have found that when applied to the mucous membrane of the tongue in considerable quantity it diminished sensibility to a considerable degree. Dentists, I am told, constantly use it for sensitive dentine. The drug is too irritating to be used on delicate membranes such as the eye, for I have proved in the dog that it is apt to bring on severe inflammation.

CURIOSITIES OF THERAPEUTICS.

BY G. ARCHIE STOCKWELL, M.D., F.Z.S.,
PORT HURON, MICH.

I. PRIMITIVE AND PSYCHO-PHYSICAL MEDICINE.

IN no way is mental evolution better exemplified than by comparison of the intellectual processes that have lifted Therapeutics from a superstition of mere barbarism to rank as a definite science. Among all early peoples we find medicine to have been intimately interwoven with those mental phenomena that procure Psychomancy: it was occult, hence a factor of religious belief developed by contemplation of the unknown mysteries of Life and Death. The same also obtains among the primitive races of the present, and the *Shams* of Kalmucks, Jakuts, and Ostiaks; *Tadibes* of Samojedes, Tchuktchi, and Tun-

gusi; *Hantus* of Malays and Dyaks; *Angekos* of Esquimaux and Innuits; *Fetiches*, *Voudoos*, and *Obi-men* of negroes; and *Powahs*, *Tlaquillahs*, *Wicaste-Wakans*, "*Spirit*" and "*Medicine-men*" of Indians;—all are exponents of therapy, at the same time exercising semi-sacerdotal functions. The same is in some degree true also of enlightened nations, as Mohammedan *Hakims*, Hindu *Brahms*, Buddhist *Bonzes*, etc., profess equal readiness to minister to a body diseased or soul disordered.

The Psychomancy of the North American savage, which, for personal reasons, is selected as a type, is universally known under the pseudonyme of *Medicine*, a term as inappropriate as it is misleading, and adopted doubtless through inability to comprehend the subtleties of a strange tongue; an error that results from the accordance to primitive people, the same mental *calibre*, and general associations of ideas, as pertain to advanced civilization and development. *Medicine* as a science finds no equivalent in any savage tongue,* and the words so translated have reference solely to the occult, mysterious, magical, and supernatural. *Medicine*, in the sense used, is of broad significance and varied application, embracing *psychology*, *clairvoyance*, *ecstasism*, *spiritism*, *divination*, *demonology*, *prophecy*, *necromancy*, and all things incomprehensible, consequently a true *Shamanism*;† it is the primitive philosophy of life and matter, and comprehends the *animate* and *inanimate*, *organic* and *inorganic*, *absolute* and *imaginary*. It holds the entire universe is permeated by spirits or essences more or less human in character, who determine the fortunes of men and operations of Nature,‡—familiar controlled by no fixed laws and in the main irresponsible, yet holding some occult and indefinable relationship one to another and to one Supreme Power, who figures under a variety

* For instance, the famous "*Medicine Dance*" of the Dacotahs is by them termed *Wacipi-Wakan*, literally "*Dance of Spirits*." *Econg-Wakan*, rendered "*medicine-making*," is properly "*conjuring with spirits*." *Wicaste-Wakan*, far from being "*Medicine-man*," should be translated "*One Familiar with Spirits*," and the same is employed to designate the civilized clergyman or missionary. The white physician, or the surgeon at the agency and military post, is known as *Pisihuta-Wicaste*, or "*One Familiar with Herbs*" or vegetable growths. So, too, the Ojibbewa or Otchipwe *maskiki*, far from being "*medicine*," has no other significance than the Dacotah *pisihuta*.

† A word derived from the Jakut through the Russian, and adopted by lexicographers as a synonyme for polytheistic myths.

‡ See Livingstone's "*Zambesi*," pp. 545 to 547.

of titles and guises, according to vagaries of race and language.*

The theory whereby inanimate and inorganic objects are endowed with familiars, pertains to all primitive peoples, and it is this that requires the belongings of the warrior to accompany him to the grave in order that he may have the phantoms thereof secured to him in his life beyond.† In this the spiritism of the savage is more consistent and complete than that of civilization. Shakespeare describes the ghost of Hamlet's father as wearing his "beaver up," and the primitive man sees no reason why a helmet should not possess a spirit as well as the warrior who places it upon his ghostly head; and in the New Zealand tale of Te-Kanawa we see the same exemplified, in that the hero devoted his personal ornaments to the spirits, who removed the essences, but left to him the substance.

Again, the impalpable essences of inanimacy may, and do, separate, appearing at

* *Manit*, *Manito*, or *Manitou* is not a universal appellation, as supposed, but peculiar to the Algonkin races; neither does it pertain to the *Supreme Power* alone, since it is *generic*, and equally applicable to all spirits. *Kitch-Manito*, however, is the "Great Spirit" of the Otchipwes, as *Owi-wis-i-manito* is of the Shawnees. *Wakan-Tanka* is the "Chief Spirit" of the Dakotahs; *Pah-ha-shun* of the Kiowas; *Ah-ho-hi-tou* of the Pawnees; *Yehl* of the Thlinkets; "*Old Man*" of the Blackfeet; "*Boy in the Moon*" of the Chepwyans; etc.

† In this connection may be traced the history of funeral offerings from its source in a crude savage philosophy down to a mere formality or symbolism. The ancient Aryan placed the implements of the individual in the grave that they might serve him in the future life. The modern Hindu has so far progressed as to lay a bit of yarn upon the funeral-cake, saying, "May this apparel be acceptable (or serve thee)." Ovid tells us that in his time the offerings had been merged into an affectionate and sentimental ceremony to appease the shades, — a sprinkling of flowers, corn, and salt:

"Parva petunt manes—pietas pro divite grata est
Munere. Non avidos Styx habet ima deos."

The early Christians buried clothing and ornaments, and playthings and toys with children, exactly as do the Dakotahs, Crees, Otchipwes, Assinoboines, and other red races to-day. The Finns, Lapps, and Chinese provide their dead with money and apparel; and the latter annually spread a feast to banquet the souls of the departed, allowing sufficient time for the phantoms of the food to be removed, when they themselves devour the substance. Precisely the same superstition obtains in many civilized districts; and in Brittany, on the eve of *Fête des Morts*, the fire is made up, the hearth swept, and the table laden with delicacies to feast the manes of departed friends. And, when we see wreaths and flowers laid upon the tomb or coffin, or strewn within the open grave, we recognize the act as a relic of the crudest savage psychomancy, and an offering, changed in signification, it is true, but nowhere broken in historical sequence.

considerable distances from their substances; and if the latter are broken, worn out, or destroyed, the spirit is no way affected thereby.‡ It is this philosophy that causes the savage to devote only his effects belonging to the service of the unknown, as exemplified by beads, bits of tobacco, fragments of cloth, furs, skins, ribbands, etc., that, suspended from wands, bushes, or trees, or displayed upon rocks, ledges, and knolls, greet the vision of the traveller everywhere in the Indian country. Dreams, too, are regarded as real events, wherein the soul or spirit, voluntarily or involuntarily, leaves the body. Trances and catalepsies are wholly involuntary, and procured by the more powerful *manits* for some express purpose of their own; and death and sleep differ only in degree and in permanency.

Spirits are good, bad, and indifferent, as the case may be, the two latter, of course, greatly preponderating. The good receive no placatory offerings, and require little attention, since their acts, influences, and purposes are obviously for the best. The evil, on the contrary, demand constant supervision and flattery, lest the smooth workings of Nature be interfered with and the normal destinies of man perverted. Again, the evil genii exhibit all the passions of humanity: some are bold, persistent, revengeful, malevolent beyond all comprehension, and but sparingly amenable to human influences; others, again, are weak, mild, vacillating, indifferent, easily satisfied. *Ni-ni-bon-jour*, or *Ninibonzech*, the "Wind-Genii" of the Otchipwes, though of the former class, was once included among the latter. Having become soured by the punishment incurred through the displeasure of *Kitch-Manito*,§ he is no longer to be depended upon with any degree of certainty. *Pah-ah-*

‡ A peculiarity of primitive theogony is that a spirit may retain individuality while yet disseminating itself in various forms, and may demand placation in each and all. Thus the Game God of the Otchipwes is ever *himself*, at the same time his spirit partakes of as many forms as there are creatures in his domain. It will be observed that the doctrine of Trinity is by no means so new as imagined.

§ He fell into evil courses, owing to the privilege he possessed of appearing in human form. One cold day, overcome by *ishkodeuwauboo* ("fire-water"), he lay down upon the cliffs that form the entrance to Thunder Bay Harbor, Lake Superior, and fell asleep. *Kitch-Manito*, discovering him in this disgraceful condition, became greatly angered, and drove his spirit to its home in the mysterious "Wind Mountains" that form the "divide" between the Lake and Hudson's Bay, and incorporated his human frame with the rocks; and his gigantic form can still be seen limned in the outline of the adjacent mountain ridge.

kuk, his younger brother, also known as *Michabo*, "The Great Hare," appears in somewhat better light, though he too is wont to be capricious. He is the analogue of the "*Brer Rabbit*" of negro folk-lore, and the Genii of Game, and through familiars, which are but essences of himself, he controls the lives of all creatures of fur, fin, and feather, arranging their migrations, breedings, and habits in consonance with his own will. The haze of Indian summer is the smoke exhaled from his pipe preparatory to winter hibernation. The brothers are greatly feared, the elder especially so, since he retains the elements within his grasp; and it is essential both should be constantly appeased and placated.

Another peculiarity of psychomancy and primitive theology is, that no portion of the universe is exempt from familiars. Every cañon, rock, hill, mountain, lake, or stream has its individual spirits or groups of spirits, and much that is grand and picturesque in Nature, or of economic value to man, is denied the savage by reason of his superstitions. The beautiful Lake of the Woods, the pellucid Nipigon, and the northern shores of Georgian Bay and Lake Superior with their contiguous islands, abound with grewsome localities; and thousands of spots throughout the water-ways of the great Northwest are regarded with awe, and avoided as if breeding pestilence. Along the west shore of Lake *Ounipeg* (Winnepeg), especially in the vicinity of Limestone Cave Point, are numberless weird and gloomy caverns, that are deemed abodes of spirits of untold malignancy. Steep Rock, on Lake Manitoba, and the valley of *Katapaywie-Sepe* (Qu'Appelle River),* are the dwelling-places of "*Little Men*,"—creatures half a yard high, with hydrocephalic heads and hair sweeping to the ground, that are ever lying in wait for unwary humanity.† Manitoba Island, in the

* The Cree tradition is that an Indian descending the stream in a canoe heard a loud voice calling among the cliffs. Listening, he heard it again as before. Shouting a reply, an answer was elicited, and though he landed and searched the rocks, neither person nor footprints could be found. From that time forth the river has been known as *Katapaywie-Sepe*, or "Who calls?" which the *voyageurs* render as *Qu'appelle*. No savage can understand that waves of air may be turned back, reflected, and sound duplicated in echo. He knows not there is an atmosphere, and to him such reverberation must needs be the voice of the unknown and unseen, consequently *spirits*.

† "Little Men or People" are supposed to be very expert in the use of minute arrows, and a sciatica, or other mysterious pain, is often laid at their door. The same ideas formerly pertained to the mounds of the White Stone River near its junction with the Missouri.

lake of like name, is supposed to be the home of a tribe of *manits* of great power and phenomenally capricious motives, on account of the sounds that are heard proceeding from it as the result of waves washing the limestone shingle of the beach, the rock beneath being honeycombed with caverns.‡ No savage foot ever ventures to press this lovely islet, or to land upon any of the demon-haunted shores of this region, save as forced thereto by accident or stress of weather. Passing canoes keep as far away as wind and wave will permit, and if driven to the strand, the unfortunates, as the occupants of these frail barks deem themselves, hasten to placate the spirits resident at the expense of the contents of their tobacco-pouches.

Also there are acts, objects, or events mysteriously linked with the fortunes of tribes and individuals that are *Shaman*, or, as it is vulgarly termed, "*medicine*," and often emblematic rather than spiritual as viewed from a civilized stand-point, though the reverse obtains in savage minds; such are calculated, among other objects, to inculcate and perpetuate unity of tradition and purpose. Thus, the grand war council of the Dacotahs, formerly a confederation of thirteen tribes and nearly or quite twenty thousand warriors, promulgated a national *Shaman*, that required a redstone pipe, with stem of ash, to be smoked at all deliberative gatherings, the real significance of which was *undying hostility to whites*.§ The Crows, or *Upsaraukas*, will not sit in council unless the pipe rests upon a dried bison "chip," and is lighted by means of a live coal of the same excrementitious material; but of what this is emblematic, remains a profound secret to this hour. Also an endeavor was made to engraft teetotalism upon their

‡ Mr. H. Youle Hinde likens the sound to "beautiful but melancholy reverberations of far-off church-bells." The same may be observed, and from like cause, among some of the limestone islands of western Lake Erie, but the tones are less sweet or distinct.

§ Mr. John Mason Browne, a gentleman from long residence among the tribes of the upper Missouri thoroughly familiar with Dacotah character, as long ago as 1865, said, "The prediction may be safely ventured that the Sioux will preserve this '*medicine*' until the nation shall have practically ceased to exist. To it may be traced the Indian war that devastated Minnesota in 1862; and there cannot, in the nature of things, and of the American Indian especially, be a peace kept in good faith until the Dacotah confederacy is in effect destroyed." For this Mr. Browne received the gratuitous scoffs and sneers of politicians and army officers, who are wont to be "wise before their time;" yet subsequent events have fully justified the truth thereof.

tribal *Shaman*, and with better success than would be imagined by those familiar with Indian character. Female chastity is, or was, the "*medicine*" of the Flatheads. Among the Mandans friendship for whites was long held a source of national and individual advantage. The lobo, or prairie-wolf, is the tutelary of the Blackfeet, one or two tribes of Plain Crees, and a branch of the Pend D'Oreilles, and its presence is encouraged about their camps and tepees, though the real secret of their regard is the incessant dolorous howls of the creature are *prima facie* evidence of security, for at the approach of man, the greatest of all foes, it sneaks silently away.*

Then there are personal *Shamans*, that may be either spiritual, totemic, or both, each individual, family, gens, or caste selecting as a familiar, some animal,—usually of the *carnivora*, as a tutelary.† With some races this is an occasion of some ceremony, and accompanied by conjuration and divination;‡ and the creature may not be killed for any ordinary purpose, nor its flesh eaten, or skin trafficked with. Many, again, make the selection untrammelled by any ceremony or rite other than fasting. There are also specific *Shamans*, independent of ruling spirits, for the purpose of recalling game, dispersing clouds, insuring rain, and to appease the manes of the departed, which last include chants, songs,§ and mortuary offerings, all of which are in some sense individual;|| and tutelars are oftentimes exchanged and discarded.

Shamanism also embodies a conception of the future state that, owing to its peculiar relations, cannot be passed by without remark. The "Land of Souls" comprehends all that is dear to the savage heart, untrammelled by exactions and vexations of mortality. The "Happy Hunting-Grounds" of poesy and fiction, with their pleasant prairies, crystal rivers, countless droves of horses and herds of fat game, perennial and luxuriant grasses and pleasant groves, where there is neither suffering nor pain, illness nor death, and general

exemption from all labor, save as may be entailed in preparing food: all are absolute realities to the primitive man, though wrapped in different guises according to the needs of tribes and races.¶ Many, both among the *Shams* and the laity, believe they have visited, or obtained more or less perfect glimpses of, this delightful land through the medium of visions and dreams, some even claiming to have conversed with the *Supreme Spirit*, who invariably appears in the guise of some familiar animal, usually one of the fur-bearing species. An aged Assinoboine was admitted by all who knew him, both of his own and neighboring tribes, to have been shown the "Land Beyond the River," conducted through it by the Great Spirit in person, and subsequently returned safely to his people. Another, an obscure individual of the Cat-Head tribe of the Dacotahs, was believed to have viewed the opening through which issue the herds of bison when called forth from the centre of the earth by *Wakan-Tanka* to feed his children.** And a Blackfoot claimed to have been transported by the "*Old Man*" to the park where the red men were taught the arts of life before they were relegated to their present abode, and whence they will return again if deserving. The Crees, a branch of the great Algonkin race, are famous for clairvoyance, or "second sight," and the facility with which they commune with the unknown; and one young brave, during a protracted illness accompanied by delirium, believed he had passed "over the river" into the "Land of Shades," and returned again expressly to depict its glories to his people. His account was so graphic as to be almost rhapsodical, and failed not to impress all who heard it with its truth.††

¶ Various ideas prevail as to the location of the "Delectable Land." The Lachoux place it above a walled canopy (the sky) encircling the world; the Thlinkets of Alaska, according to W. H. Dall, consider it a park hidden away about the head-waters of the Nasse River; the heaven of the Dacotahs and Chinooks is at the centre of the earth; that of the Dog-Ribs beyond the ice that encircles the Pole; and of the Crees and Otchipwes somewhere towards the tropics.

** It will be observed the Sioux long since anticipated "Prof." Syme's wonderful (!) discovery.

†† The following is a literal translation:

"I was ill, and fell asleep. I awoke on the bank of a deep river, whose waters were flowing swiftly and black from a great mist on the south, to a great mist on the north. Many were there before me, gazing at the flood, or the gloomy shore that lay wrapped in mist upon the farther side. Now and again the clouds would roll away, revealing the mouth of another great river

* See Appendix A.

† I once witnessed a meeting between two Indians of different tribes, an Ottawa and Otchipwe, neither of whom had ever seen the other. After shaking hands, they announced themselves *brothers*. Subsequently I discovered the relationship assumed arose from both being members of the same *gens*—"The Beaver"—in their respective tribes.

‡ See page 235 for ordeal of conjurers, which is almost identical with these rites.

§ See Appendix B.

|| See Appendix C.

There is a widely-prevailing belief, by no means confined to the ignorant and vulgar, that the savage is preternaturally wise in the secrets of Nature; that he is inherently endowed with faculties whereby a glance suffices to determine the value of any plant, growth, or mineral within the domain of his nomadism; and that his pathological information rises superior to anatomical or physiological considerations, transcending all that has been wrung from centuries of applied research on the part of civilization. Society is wont ever to turn a deaf ear to science and evidence, when the superstitions, that are in some measure inherent to every member of the human race, are called in question; and charlatanism receives its greatest impulse when found upon theologio-scholastic ground, since the clergy have not yet learned that adherence to primitive therapeutics is virtual abandonment and denial of the claims of Christianity. If such is an inherent gift of divinity, so also psychomancy must needs be the true philosophy of the soul! "Prayer-cure" and "mind-cure," far from being new,

pouring its angry waters into the one at my feet. To the south of this river all was bright, beautiful, and glorious; to the north, dark, gloomy, and forbidding. On the one hand was the happy hunting-grounds; on the other, the abode of evil.

"Time after time my companions sought to cross the swift waters to the happy hunting-grounds. Some arrived safely; others were carried to the north, and disappeared in the mists that shrouded that loathsome country.

"At last I ventured. Alas! the current was too swift. The recollection of my evil deeds overwhelmed me. I was unable to stem the swift waters; I was swept to the north shore of the opposite river.

"I scrambled up the bank. Many moons were passed by me hunting in that dreary land. Success rarely crowned my efforts; I was ever on the verge of starvation; in danger of foes, or wet, or cold,—always miserable.

"At length I came upon a river like the one I had crossed,—with mists, and the mouth of a great stream opposite. Breaking clouds soon revealed happy hunting-grounds on the one side, and a still more gloomy and terrible land upon the other. Many sat upon the bank gazing at the troubled flood; others attempting to cross. Some succeeded. But a few were swept away to the region of desolation. These were very bad people.

"I threw myself into the current. I knew I had done well in this dreary hunting-ground, and it gave me courage. I swam boldly and strong!

"Soon I landed upon the shore. My heart became light. My sorrows disappeared as I climbed the green slope. Before me I saw Indians numerous as grass-leaves; bison on the distant plains plenty as rain-drops in summer; a cloudless sky was above me; a warm, happy, scented breeze blew in my face. I threw myself upon the ground and slept. When I awoke I was here in my lodge on these plains again."

were both practised, undoubtedly, at the time when man chased the reindeer on the plains of middle Europe.

Somewhat extended knowledge of and experience in the phases of psychomancy as exhibited by the primitive races of America, permit me to speak definitely regarding their therapeutics. In no essentials do they differ from the practices of other races of low organism and development, whether found in Central and Northern Asia or in the jungles of Africa and Polynesia; and the variations noted are merely the sequels of psychological and tribal peculiarities. Consequently it may positively be asserted that the superstitions and bigotries of civilization pertaining thereto are without foundation in either analogy or fact, since they rest only upon the frail foundation of coincidence.*

The savage recognizes no influences, even in the simplest affairs of life, that are not derived from the supernatural and occult. He knows nothing of the relations existing between cause and effect. Physiological and pathological phenomena, and their sequences, are wholly beyond his mental grasp. Even his language is without an equivalent for remedies as *remedies*, or means of defining remedial results; and therapeutic manifestations are deemed but the conflicts of spirits, and the vanquishment of the weak. To him, disease is not morbid phenomena, but the individual or specific manifestation of some obnoxious demon who, through accident or design, has eluded the watchfulness of the tutelar, and established and fortified itself in the part affected. Under such circumstances, as may be imagined, most absurd ideas prevail, and measures adopted for relief are wholly irrelevant. Were I to repeat the barbarities practised to secure the most simple results, or the brutalities entailed by innocuous arrow-head punctures and superficial wounds, or the filthy and even obscene practices that obtain for the relief of everyday indispositions, they would scarce be credited.† Scarification, hacking of limbs (and

* Few have any conception of the prevalence of coincidences. In reality they are more numerous than facts, as any student in the pathological laboratory well knows, and are one of the chief evidences of occult relations existing between *mind* and *matter*.

† The following from the pen of simple and honest Samuel Hearne ("Hearne's Journey"), though the *half* is not told, is sufficiently illustrative:

"The natives themselves (Dog Ribs) never make use of any medicines. . . . Nature alone works the cure." (P. 338.) "They use no medicine either for internal or external complaints, but perform all cures by means of

even the whole body), with flints and knives; the actual cautery,—hot irons, stones, or ignited touch-wood; and the hot vapor-bath, which has less a hygienic and therapeutic significance than as an act of worship; such are the *simplest* of surgical resorts. Think, for instance, upon the “inherent native skill” (as often quoted) that caused the soft parts of the throat, including fauces and soft palate, to be forcibly wrenched out by a pair of bullet-moulds in the hands of an “Indian doctor,” and all to relieve a tickling cough arising from relaxation of the muscular tissues of the pharynx and an elongate uvula!* And this was not provoked by any appreciation of the real difficulty, but was calculated to remove, and render the parts uninhabitable to the demon that had taken up its abode therein. It is perhaps unnecessary to add the operation was in every way a success, for it not only secured the dislodgment of the spirit of the malady, but that of the individual likewise; and the death of the unfortunate was deemed the sequel of extreme malignancy on the part of the former.

The so-called “Indian doctor,” who penetrates our cities and towns, or perambulates the villages and rural districts, preying upon the superstitions of civilization, if really a red man, is never a true *Sham* or “*Medicine-man*,”

charms. In ordinary cases, sucking the part affected, blowing and singing to it, hawking and spitting, and at the same time uttering a heap of unintelligible jargon, compose the whole cure. For some inward complaints, such as griping in the intestines, difficulty of making water, etc., it is very common to see these jugglers blowing into the *anus* or into the *parts adjacent* till their eyes are almost starting out of their heads; and this operation is performed indifferently on all without regard to age or sex. The accumulation of so large a quantity of wind is at times apt to occasion some extraordinary emotions, which are not so easily suppressed by the sick person; and as there is no vent for it but by the channel through which it was conveyed thither, it sometimes occasions an odd scene between the doctor and patient, which I once wantonly called a *bombardment*, but for which I was exceedingly sorry, as it highly offended several of the Indians, particularly the juggler and the sick person, both of whom were men I much esteemed; and, except in that moment of levity, it had ever been no less my inclination than my interest to show them every respect that my situation would admit. I have often admired the great pains these jugglers take to deceive their credulous countrymen, while at the same time they are indefatigably industrious and persevering in their efforts to relieve them. Being naturally not very delicate, they frequently continue their windy process so long that I have more than once seen the attendant quit his patient with his face and breast in a very disagreeable condition! (P. 190.)

* A fact.

but some knave, who has profited by association with the whites, taking a leaf from the book of the pale-faced charlatan. By assumed stoicism, dignity, imperturbability, and brevity of speech, the reasons for which last are obvious, along with glances replete with concentrated wisdom, he has little difficulty in securing dupes and following. He is nearly always a drunken scoundrel and *ex-protégé* of some missionary society, one who, among his own people, receives the scorn and contempt due a renegade, not one of whom would accept the *dogwood* bitters, *tag-alder* teas, *prickly-ash* stews, *crowberry-bark* decoctions, *sumac* infusions, and *mandrake* physic, which he so lavishly distributes in all their crude nauseousness to his white admirers.

Again, the position and ease attendant upon a reputation for *Shaman* is wont to develop pretenders and charlatans in the lower as well as upper ranks of society; but such are in no sense “*Medicine-men*,” nor do they often secure permanent or respectable following. Many a warrior, revered and respected in council and tribal deliberations, has become the butt and jeer of an entire community as a sequel to pretensions to “*medicine*.” On the other hand, a well-known poltroon, inferior in intellect perhaps, through innate or acquired faculties (from *epilepsia*, oftentimes) that fit him for the position, obtains admittance to the ranks of the fraternity of *Shams*, thereby becoming an oracle whose behests may not be assailed or controverted, even by chiefs; and his influence extends not only to his own immediate clan, but to neighboring tribes,†

† Of the influence one such personage may exert, I cite an instance from personal knowledge. A band of Swampies, a branch of the Cree nation, were in the habit, annually with each autumn, of resorting to “Pike’s Head,” near the mouth of Jack Fish River, on Lake Winnipeg, in order to subsist upon *Ah-tik-a-meg* (white-fish), which could here be had in abundance when other foods were unobtainable. In the midst of one of these migrations (in 1860, I think), they were overtaken by a runner bearing a message from the “Beaver,”—a noted “*Medicine-man*” of the Upper Saskatchewan district,—forbidding nearer approach to the lake, or the taking of fish during that winter, on pain of his displeasure and the evil he would invoke. Though the threat was in no way specific, and merely the sequel to petty enmity and spite, its very ambiguity made it the more alarming. The poor Swampies made haste to break camp and return to their summer hunting-ground, though knowing such would entail the perils of starvation. The result was great suffering and privation: many died from want before their condition became known to the Hudson’s Bay Company authorities, and succor was had from this source. (See account of the “Black Snake” in Appendix.)

and perhaps even to the camps of hereditary enemies.

The true *Sham*, or "*Medicine-man*," is little understood by civilization, since he exhibits a phase of savage life that is rarely permitted to come under casual observation. Very far from being a mere knavish varlet, conspicuous for unblushing impudence and petty chicanery as commonly depicted, he is instead a staid, earnest, shrewd, far-seeing man, more than ordinarily endowed, with perceptive faculties sharpened by observation and training, and accustomed to receive impressions and draw conclusions from matters so trivial as to elude general comprehension.* As a rule, he is honest,—as the world goes,—and a firm believer in the truthfulness and advantages of his calling. The deceptions he practises are unavoidable, and less with a view to delude humanity, than to cajole and beguile the unseen and unknown. He is a "mind-reader," psychologist, mesmerist, and clairvoyant in one,—of no mean ability; an endowment that, though sometimes inherent, is oftener inculcated and developed through *ecstasia*.†

* Herein lies the secret of deductions that, made without apparent basis, are so accurately drawn as to fairly appear marvellous; but the credit thereof is always given to the familiars who, he believes, constantly attend him. Knowledge, however gained, even if through personal study and application, is necessarily a spiritual gift. If it were not, he argues, why do some acquire easily, some not at all? Consequently, whatever his acts or professions, the *Sham* is always consistent.

† The practice of *ecstasia* is universal in all lower stages of culture as the outgrowth of anxiety to peer into the future. It is what procures camp-meeting "*power*," and "*glory*," that attracts the negro to his houses of worship; sustains the Dacotah under the tortures of the "*Sun Dance*," and promote the labors of "*evangelists*," beside being a derivative of many forms of *mania*, *dementia*, and *hysteria*. To one of its many forms (more particularly *epilepsia*) the religions of the world, past and present, owe their rise,—Judaism, Egyptian and Greek mythology, Lamaism, Buddhism, Christianity, Mohammedanism, and also the sects that have sprung from the Reformation, down to Shakerism. *Theosophy*, which boasts it "will yet sweep the world," far from being advancement, is retrogression, and promises nothing that was not probably known to the earliest nomad, or that is not patent to modern primitive barbarism: it is but primitive psychomancy in a new dress. The savage recognizes that clairvoyant and psychic conditions may be inculcated and developed spontaneously (through various mental and physical processes, by any act or affection that procures anæmic disarrangement or disorganization of the great nerve-centres), hence for this purpose he resorts to fasting, long vigils, and self-inflicted physical tortures. We frequently discover these peculiarities in the midst of civilized society. Two patients of my own exhibited such in marked degree. One, a finely-educated lady, of excellent mental balance and culture,

To the prejudiced vision of critical civilization he may appear an object of contempt and ridicule, owing to incongruities of behavior and costume, yet it must be remembered that frippery is a concomitant of barbaric splendor, pomposity of savage dignity, and asceticism and indifference but synonyms of pride and austerity. The very state of society by which he is surrounded entails all these as necessities, and if he is curt and rude, it is because his position and prosperity is founded upon the superstitions of his calling and following.

The dignity and power that accrue to the profession of psychomancy, by reason of autocratic relations no way limited by tribal considerations, render it the noblest aspiration of the young savage. Even pale-faces have sought to be enrolled within the mystic brotherhood (for such it is) as a means of extending their influence, though few, so far as I am aware, have ever been admitted to the higher and inner mysteries without first being adopted into the tribe and undergoing the prescribed ordeals.‡ Women, as a rule, are excluded, though now and again, by virtue of some extraordinary gift, one sometimes obtains *quasi* recognition. I never knew but one "*medicine squaw*," she of the Salteaux Otchipwes, supposed to have accomplished a quarter more than a century of life,—a claim fully justified by her appearance. Toothless, wrinkled, every way hideous and repulsive, cordially hated and feared, the malignancy of her disposition was such that even when *articulo mortis* she cursed and menaced with a long stick kept by her side for the purpose, the children and dogs that ventured near her *lair*. For many years all but bedridden, she passed her time in solitude and neglect in a rude wigwam on the outskirts of the village, her only covering and garment a filthy caribou-skin robe, her support, merely what she could gather or wring from the tribe by threats. She also boasted numerous acts of cannibalism, by which it was popularly held she had obtained a lease of life that could be terminated only at her own option. Her death was the sequel of a bullet-wound inflicted by a French half-breed she had threatened to

who sought to mitigate the pangs of a great bereavement by excessive devotion to religion; the other, a gentleman of superior brain-development and physique, who was given to occasional deep and prolonged alcoholic and venereal excesses that were invariably followed by psychic and mesmeric phenomena, including voluntary clairvoyance.

‡ See Appendix D.

"bewitch," whereby the latter gained a reputation for bravery that, however, would have stood him in little stead but for the interposition of a prominent *Sham*, who averred the crime would prove a blessing to the tribe; and by order of the latter the body was cremated in the flames of her own dwelling, that her spirit might not secure lodgment in the neighborhood.

Except in special instances, recognition by the brotherhood of *Shams* requires a more or less extended novitiate; but even this favor is not obtained without difficulty, as there is manifest disinclination on the part of the fraternity to increase their number, and thereby divide power and profit. The friends of the aspirant are always ready to promote his interests, even to the sacrifice of personal wealth, since the position is one of honor and emolument, from which they expect to derive due advantage, and consequently heavy bribes are not infrequently tendered, and as often, perhaps, rejected.

Consent obtained, the candidate enters upon his duties by becoming an assistant, or *acolyte*, to one or more of the brotherhood, by whom he is carefully studied to discover his abilities. The apprenticeship is arduous, beset throughout by trials and stumbling-blocks calculated to tax to the utmost the patience, faith, endurance, and fortitude of the individual, and betray his inner consciousness and latent foibles. When sufficiently advanced, he is commanded to proceed, surreptitiously, to some one of the mysterious solitudes accredited with being the haunt of the particular *manit* whose favor is sought, there to offer sacrifice, beside which he must remain constantly, without shelter, unprotected from the elements, fasting,* and alone until the spirit vouchsafes its pleasure by revealing itself personally in its animal form,† or in dream or vision. Here some fail, for the ordeal is no trifling one. If overcome by

fears engendered through disordered imagination, or by suffering, hunger, and exposure, or the spirit declines to manifest itself in the accustomed manner, no second essay is ever permitted. Individuals have been known to perish in the midst of these vigils (a most honorable death) rather than face the disgrace that inevitably attends such misfortune; and deception is unknown, since it is believed it must react with fatal effect upon its author. Commonly, however, the desired result is attained with little difficulty, since the situation and surroundings, and the bodily and mental torture induced, serve to disorder the nerve-centres whereby *ecstasia* is procured.‡

Strictly speaking, the novitiate is now ended, and the individual assumes rank as a conjuror, though first he must seek a specimen of the creature of his vision which shall fulfil certain conditions of age, sex, and de-

‡ It has been supposed that narcotics bear a chief part in the production of *ecstasia*, but this is entirely gratuitous. Powell ("Bureau of Ethnology," 1879-80, p. 36) purloins the idea from George Hartwig, and adds, "Civilized man has thus inherited an appetite for narcotics to which the enormous propensity to drunkenness existing in all nations bears witness. When the great actor in his personification of Rip Van Winkle holds his goblet aloft and says, 'Here's to your health and to your family's, and may they live long and prosper,' he connects the act of drinking with a prayer, and unconsciously demonstrates the origin of stimulants. It may be that when the jolly companion has become a loathsome sot, and his mind is ablaze with the fire of drink, and he sees uncouth beasts in horrid presence, that inherited memories haunt him with visions of the beast gods worshipped by his ancestors at the very time when the appetite for stimulants was created."

And *this* is science! In his anxiety to establish a *point*, the author drags the prayer or invocation that attended the libations of ancient civilizations, into the mythology of the primitive man past and present, and establishes it as a sequel to *ecstasia*. Apparently he is not aware that *cerebral hyperaesthesia* is a concomitant of brain *anemia*, rather *hyperamia*, and that the latter is usually fatal to *ecstasia*; that *stimulation* is very far from being *narcotism*; and that physiologists will be surprised to learn that *mania a potu* is a "*mind ablaze with the fire of drink*!" While narcotics may procure transitory delirium or mania, neither constitute *ecstasia*, even though ecstatic. No primitive race known to civilization ever resorts to any methods other than fasting, and physical and mental mortification, to secure *ecstasia*; yet many are familiar with both stimulants and narcotics, and employ them for purposes of intoxication. I am not prepared to deny the human family has the love of stimulants as a heritage, however, for the evidence in this respect is fairly overwhelming when we consider that *eight hundred millions* are addicted to tobacco, *half that number* to opium, *five-eighths* as many to tea and alcohol, and *sixty millions* to coffee, and yet the devotees of *coca*, *bang*, *hashish*, *betel*, "*muc-a-more*," and *awa* are not considered. (*Vide Jour. of Inebriety*, for 1877.)

* W. H. Dall ("Alaska and its Resources," p. 425) says that among the Tlinkets it is permissible for the aspirant to sustain life by means of the roots of *Panax horridum*,—one of the gensing family; but this is not true of the red races generally.

† Certain creatures represent the multiple essences of a very powerful spirit,—such as beaver, bear, marten, mink, weasel, fisher, musquash, otter, wolverine, fox, black- and rattlesnake, sturgeon, dog-fish (*Amia ocellicauda*), lake sheephead (*Haplodonitius grunniens*), etc. The hare also is a powerful representative, and figures prominently in the mythologies of all North American nomads, and likewise appears in the superstitions of Southern and West India negroes, who doubtless derived them from the coasts of Africa. (See *Pah-ah-kuk*, p. 230.)

velopment, be killed in a certain way, and its skin dressed in a peculiar manner. Subsequently, when ornamented with savage gauds, it becomes the "*spirit*," or "*medicine-bag*"* of the conjuror, that thereafter is constantly worn suspended from the neck. Also a portion of the animal's flesh is devoured raw, in order that the spirit thereof may incorporate itself with that of the *Sham*, when it becomes the inspiration of all his acts and intercessor at the courts of the supernatural.

Subsequently progressively higher degrees in psychomancy may be had by those who evince capability therefor, which are instituted at special or stated gatherings of the fraternity, and within a sacred "*medicine-lodge*;" and these mysteries have never been penetrated by any unauthorized person, and are always savagely revolting. Not only are the customary drummings and rattlings to be heard, accompanied by howls and dancing, but also the shrieks and moans of creatures tortured and vivisected for purposes of divination: there is a great similarity between some of these practices and those of howling and dancing dervishes of the Orient. The whole invariably winds up with a feast, to which the laity are admitted, when feats of

* The "*medicine-bag*" is the repository of amulets by the possession of which the immediate favor of *their* spirits are secured; and these are by no means constant, since they are changed as often as the familiars prove capricious or refractory. No two bags ever exhibit the same array of contents, though certain articles, such as the rattles and fangs of serpents, claws of the beaver, teeth of the bear or raccoon, and bunches of hare's fur, are usually common to all. One recently in my possession contained the following: bit of skin from hough of moose; tip of caribou ear; ditto of lynx,—the hairy tuft; two incisor teeth of some rodent,—probably flying or red squirrel; four beaver teeth; fangs and tail-tip of rattlesnake; two fossil pteropods,—supposed to become moths after twilight; fur from tip of tail of a mink, tied with horse-hair; portion of dried entrails of some fish, species unknown; two ear-bones of the Great Lake sheephead (*Haplodonitius grunniens*),—"great medicine," and to which whites attach the superstition of "good luck" insured by their possession; portion of the cartilaginous vertebræ of lake sturgeon; claw of wolverine,—"very powerful medicine;" a nugget of native copper; ditto of silver in copper matrix; copper arrow-head,—"mound-builder's;" rounded and polished piece of magnetic iron,—"grape ore;" crooked nail; button with monogram V.R.; claw of cray-fish; vertebræ of lake lizard,—*menobranchus*; bit of feldspar; ditto amethystine quartz; three splinters of seyenite; two packets containing powder, one white, one yellow, carefully wrapped in birch bark and tied with sinew,—one responds to arsenic tests, the other appears to contain sulphate of cinchonidia along with an alkali, neither a savage product; two water-worn splinters of juniper; and lastly, three beautiful *aspidolites* or *chlorophyllites*,—"big medicine."

gormandizing are in vogue that would fairly astonish the digestion of an anaconda. One of the mysteries, more especially obtaining among the Crees, Otchipwes, and Chipewyans, is sometimes practised in public on the eve of the annual "*Goose Feast*," that requires the candidate to devour a whole *live* dog; and a more hideous or fiendish procedure, as viewed by the firelight, attended by the shrieks of the victim and howls of the multitude, cannot be imagined.

APPENDIX.

A.

The great *Shaman* of the Chepewyans is the "Boy in the Moon." The tradition is that an old woman found a boy in the forest, brought him to camp, and cared for him. The lad made for himself a pair of snow-shoes of such preposterous dimensions as to excite the mirth and ridicule of all who saw them; the tallest man in the tribe could not have used them. He could give no account of himself, or where he came from, and altogether he was regarded as mysterious and uncanny, and consequently avoided.

Whenever the tribe suffered for food, and the best hunters could kill no game, some one would be sure to discover a strange track, with steps a prodigious distance apart, that invariably led to a newly-killed deer. There the steps ended, and no further trace of the unknown hunter could be found. Finally suspicion fastened upon the strange boy and his enormous snow-shoes, which corresponded to the track; and when placed under surveillance it was found he was in the habit of stealing secretly from the camp, returning again in some mysterious and incomprehensible manner, leaving no trace, and defying the utmost watchfulness. On such occasions also a newly-killed deer was always discovered.

Though identified as their unknown benefactor, he still was neglected, poor, and ragged. But the following winter, at a time when the hunters had met with great success and killed a number of caribou, he begged for a bit of fat, which was unkindly and arrogantly refused. That night he disappeared, and no vestiges, save his ragged clothing, thrown upon a heap of refuse and offal, could be found.

A moon later he suddenly reappeared, but well dressed and grown to man's stature. He now informed the people his disappearance was caused by his return to his home in the moon, whence he should shortly return, and that he would continue to afford them countenance and protection as long as they were deserving. When in distress, they might appeal to him, when he would be the judge of their needs; but, as punishment for having refused him a piece of fat when he sought it, all deer should thenceforth be lean in winter and fat only in summer, which is true of the caribou to this day. Since then he has continued to reside in the moon, where his face may sometimes be seen; and the hunters are his especial care, and with an offering of fat rarely fail to secure his favor.

B.

The following is the song of a Blackfoot squaw as sung to appease the manes of her son who was killed by the Crows or Upsaraukas:

"Many scalps will be taken for your death:
The Upsaraukas will lose many horses:

Their squaws will weep for their braves:
They will curse the spirit of Isthumaka!
O my son! I will come to you,
And make moccasins for the war-path,
As I did when you struck the lodge
Of the 'horse-guard' with the tomahawk.
Farewell, my son! I will see you
Beyond the 'Broad River.'

"O my son, farewell!
You have gone beyond the 'Great River';
Your spirit is far beyond the Sand Buttes;
I shall not see you for an hundred winters;
But you will scalp the foe in the green prairie
Beyond the 'Great River.'
When the braves of the Blackfeet meet;
When they smoke the spirit-pipe and dance the war-dance;
They will ask, 'Where is Isthumaka?
Where is the bravest of the Mannikappi?
He fell on the war-path!'"

Said the gentleman from whom the foregoing was obtained, "Sung in a plaintive minor with wild irregular rhythm, the dirge was far more impressive than mere words can convey."

C.

The majority of whites brought in continuous and intimate relations with savages and nomadic life, notwithstanding education, prior teachings, and iron-clad creeds, are wont to imbibe more or less of the superstitions of *shamanism*, and oftentimes surpass the nomads themselves. This may appear strange at first thought, yet we find the same occurring in the midst of the most advanced civilizations under the guise of Spiritism and Theosophism, "Vitipathism," etc. The "Free Trapper," so graphically described by Washington Irving, though now all but extinct, was wont to ostentatiously out-medicine (so to speak) even the red man. His horse and its caparisoning and ornaments were each and all "medicine," also his apparel from cap to moccasins, and the sash, and the knife, axe, and pipe suspended therein. By means of "medicine-powder," a "medicine-gun" was made to propel "medicine-bullets." And from his neck depended a "medicine-bag," with *medicine* for almost every imaginable phase of life and existence, including accidents by flood and field, to secure success in trapping, to procure rain or sunshine, etc.

D.

Sometimes a very trifling circumstance will unwittingly, perhaps, elevate a white man to rank as a *Sham*, and if possessed of tact and ability, he may be acknowledged by the red "brethren of the profession." A foolish and petulant remark gave one Meldram, an employé of the American Fur Company at Fort Benton, the favorite *medicine-man* of the Crows, a position he accepted, and held for years to their satisfaction and his own profit, his amulets being a silver watch of the "bull's-eye" pattern and an almanac, which latter, by reason of the cut of a human form partially eviscerated and surrounded by the signs of the zodiac that appeared upon the title-page, was deemed "most powerful *medicine*." During the construction of a heavy press for baling furs he was constantly pestered by curious savages. Finally a number of Crows began making inquiries at a moment when he was busy getting a heavy beam in place, and he curtly replied it was a *medicine* that would cause snow to fall to a depth marked by the knotted cord attached to the lever. The fame of the "snow medicine" rapidly spread. Hundreds came to see it from a distance, and all looked forward to winter with no little anxiety. Strange to say, snow *did* fall to the depth indicated,

about a yard, and though it touched the knot of the rope, never rose any higher.

By no less a bit of foolishness I found myself famous. Two of us were staying with an illicit vendor of alcohol in the Indian country, our host being a strong partisan of A. J. Davis and Richard D. Owen. For want of better amusement, we were wont to chaff him upon his belief, and one evening sat down to a small pine table and procured all the phenomena of "spirit-rapping," "table-tapping," etc., somewhat to our own astonishment, for neither had ever essayed the feat before, and greatly to the delight of our landlord, who vowed we had heretofore "been testing" him. The last to leave the table, as I rose that useful article of furniture insisted upon following me some distance across the room. A dozen Otchipwes had witnessed the performance, and now they hurried out of the house, shaking their garments, and exclaiming, "*Spirits! spirits!*" The day following I met one of the dusky audience, who requested a charm to drive away rheumatism, to which I responded by handing him a *cachou aromatique*. An hour later another proffered the same request, seizing my hand, and adding, "*Ah, Do-ah-tor, I 'fraid of yoh: yoh great med's'n,—mak gôs* (ghosts)!" A few years later I found both had been permanently relieved, and that the pellets, minus their silver coating, were still in existence and accredited with many wonderful cures!

PORT HURON, MICHIGAN.

(To be continued.)

THE ANTIPYRETIC ACTION OF ANTIFEBRIN.

BY DR. E. W. EVANS, EASTON, PENNA.

(From private laboratory of Dr. Ott.)

PART I.—ON THE NORMAL ANIMAL.

THE many favorable reports on the clinical action of the new antipyretic acetanilide, perhaps more familiar under the name of antifebrin, have led me to make a few experiments with it in order to ascertain as far as possible its mode of action, more particularly in temperature reduction.

Acetanilide is not by any means a new substance, having been known to chemists for a long time; but it is only recently that its physiological property as an antipyretic was discovered.

It is a neutral body, not acted upon by hydrochloric or sulphuric acids, and not affected by alkalis, except when greatly concentrated. Occurs as a fine white crystalline odorless powder, imparting a slight burning sensation to the tongue. Dissolves in ether, alcohol, benzene, benzol, and essential oils, but is insoluble in cold and only sparingly soluble in warm water, from which it crystallizes again at 108° F.

Its chemical constitution is $\text{NHC}_6\text{H}_4\text{C}_2\text{H}_5\text{O}$, and is obtained in an impure state by the

action of aniline upon glacial acetic acid in the presence of heat; and from this the pure article may be secured by crystallization from benzol or boiling water.

Hence the drug belongs chemically to the acetanilides or phenyllacetamides, differing greatly in this respect from the other antipyretics, which belong either to the phenols (carbolic acid, hydrochinon, resorcin, salicylic acid) or to the chinoline order (antipyrin, chinolin, kairin, quinine, thallin).

Considerable difficulty was at first encountered in the administration of the drug in the solution used (1 gramme to 50 c.c. warm water) owing to its high point of crystallization; this, however, was overcome by frequent applications of heat to the solution, together with further dilution, one-half usually being sufficient to maintain the drug in solution at a temperature not too high for injection.

Preliminary to the experiments on heat production and heat dissipation I have made one or two in order to note its general action on the heart and respiration.

Experiment 1.—Rabbit; weight, 2.72 pounds.

Time. P.M.	Temp.	Remarks.
2.25	103.4°	
2.37	Injected .12 gramme antifebrin hypodermically.
2.47	102.4°	
2.5406 gramme hypodermically.
3.10	102.2°	
3.2006 gramme hypodermically.
3.3806 " "
3.45	101.6°	
3.53	Slight drowsiness.
4.06	101.6°	
4.3515 gramme injected into jugular.
4.41	Perfectly relaxed; reflexes still manifest.
4.45	97.3°	
4.50	Pulse 188; respiration 64.
5.05	95.8°	Pulse 172; respiration 64; all reflexes abolished.
5.30	Pulse 144; respiration 56; .75 gramme in jugular.
5.35	Pulse 132; respiration 16; gasping and irregular.
5.45	94.4°	Respiration more regular.
6.005 gramme injected into jugular.
6.01	Respiration almost ceased; heart still regular but weak.
6.03	Rabbit dead; heart immediately exposed and found not beating.
6.10	Examination of urine revealed no sugar, but the manifest presence of albumen.

It will be seen that in this experiment 1.7 grammes of antifebrin were exhibited to an animal weighing only 2.72 pounds, within a period of three and one-half hours, before death ensued. It would seem at least that

the drug is not a very dangerous one in its effect upon either the heart or respiration, especially since the doses used were extremely large in comparison with those found necessary to obtain the desired effect in its clinical application,—11 grains producing a fall of 2.4° C. in three hours in a man aged nineteen years suffering with typhoid fever. About four times that amount of antipyrin being required to produce an equal reduction.*

In the experiment given above .3 gramme caused a fall of 1.8° F. in one hour and twenty minutes without having any perceptible influence, either general or upon the heart or respiration.

Experiment 2.—Rabbit; weight, 2.5 pounds.

Time. P.M.	Temp.	Remarks.
2.30	100°	The rabbit's temperature was 102° previous to the introduction of the canula into the jugular.
2.3512 gramme antifebrin injected.
2.48	99.6°	
3.0012 gramme into jugular.
3.05	Partial relaxation; staggering.
3.13	99.8°	
3.45	100.6°	
3.5012 gramme injected into jugular.
4.30	101.3°	Rabbit lively as ever and returned to pen.

In the second experiment the same amount of antifebrin that had caused a fall of 1.8° in the previous one produced in the same time a fall of only .4°. The general effect, however (to note which was the object of these experiments), was almost equally unnoticeable.

The results here obtained, at least in the first experiment, are at slight variance with those of Cahn and Hepp, as regards temperature reduction in the normal animal.

Again, in the calorimeter experiments I never failed to get some reduction (from .4° to 1.6°) when small doses were employed.

It is quite possible that this disagreement may be entirely due to a difference in the amount of drug exhibited, since large doses elevate temperature. However that may be, it is evident that the toxic effects of antifebrin are not manifested by such doses as are required to secure the necessary reduction in fever.

I next proceeded to study by a few calorimetric experiments the effect upon heat production and heat dissipation.

The calorimeter used is known as *D'Arsonval's*. The receiver is formed by the inner one

* "Clinical Experiments of Cahn and Hepp," *Centralblatt für Klinische Medizin*, August 14, 1886.

of two concentrically arranged copper cylinders, the outer one being about one-third greater in diameter, thus creating a second annular chamber between the two, which is filled with water for the purpose of maintaining a uniform level of temperature to the calorimeter. Through the inner chamber the air is drawn over the animal, and pumped out through the large metre of 'Voit's respiration apparatus by a water-wheel attachment. The D'Arsonval gas-regulator I will not describe, since it never worked satisfactorily and was not used in any of my experiments. The thermometric observations were made on Geissler's thermometers, which were previously carefully tested at the Yale Observatory and the necessary corrections made.

I will exemplify these experiments by rendering the first one in detail, and in the succeeding ones simply make use of the results obtained.

The method of calculation employed in these experiments is practically the same as that of Dr. H. C. Wood.

Experiment 3.—Rabbit; weight, 3.26 pounds.

Time.	Air temp.	Exit temp.	Cal. temp.	R. temp.	Metre.
1.24	74.35°	68.95°	69.25°	104.4°	868.204
1.39	75.05°	71.65°	69.45°
1.54	75.25°	72.01°	69.65°
2.09	75.45°	72.19°	69.85°
2.24	75.45°	72.01°	70.05°	104.6°	869.100
	75.11°	71.36°	69.65°	.2° gain.	896
	71.36°		.80° gain.		
			.30° gain corrected.*		

3.75° loss.
2.40 .045 gramme antifebrin injected hypodermically.

Time.	Air temp.	Exit temp.	Cal. temp.	R. temp.	Metre.
3.06	75.35°	70.93°	70.35°	105.0°	869.100
3.21	75.05°	73.45°	70.75°
3.36	74.95°	73.81°	70.95°
3.51	74.75°	73.09°	71.15°
4.06	74.55°	73.09°	71.35°	104.4°	870.629
	74.93°	72.87°	70.91°	.60° loss.	1529
	72.87°		1.00° gain.		
			.64° gain corrected.		

2.06° loss.

* By making a series of experiments in which there was no animal placed in the chamber of the calorimeter, and no air pumped through, it was observed that the calorimeter temperature in one hour rose .09° for every degree that the air temperature stood above that of the calorimeter; discovering the fact that the calorimeter rise was due to three factors instead of two, viz., heat given to the calorimeter by the animal, heat given off by the air passing through (always at a temperature about 3° higher than that of the calorimeter), together with a relatively large amount of heat taken from the surrounding air. This last factor was always overcome by making this .09 correction on the calorimeter gain previous to the calculation of heat units given to the calorimeter.

Before injection :

$$\begin{aligned}
 V' &= 896 \text{ litres of air pumped through the large metre.} \\
 t' &= 71.36^\circ - 32^\circ = 39.36^\circ, \text{ number of degrees the air is heated above } 32^\circ. \\
 V + (V \times 39.36 \times .000035 \text{ coefficient of expansion}) &= 896. \\
 V + .0800976 V &= 896 \\
 1.0800976 V &= 896 \\
 V &= 896 \\
 \frac{1.0800976}{1.0800976} &= 829.6266 \\
 W &= V \times .002851, \text{ weight of 1 litre of air at } 32^\circ \text{ F.} = 2.3552 \text{ pounds.} \\
 Q &= 2.3552 \times 3.75 \times .2374 = 2.0867, \text{ heat units taken from the air.} \\
 Q &= W \times t' \times \text{Sph.} \\
 Q &= 37.5 \times 1 \times 1.002 = 37.575 \\
 Q &= W \times t' \times \text{Sph.} \\
 Q &= 43.5 \times 1 \times .095 = 4.1325 \\
 41.7075 & \text{ Heat units required to raise the calorimeter } 1^\circ. \\
 41.7075 \times .3 &= 12.51225 \text{ Heat units given to the calorimeter.} \\
 2.08670 & \text{ Heat units taken from the air.} \\
 10.42555 & \text{ Hourly heat dissipation.} \\
 \text{Heat added to reserve} & .54110 = (3.26 \times .2 \times .83) \\
 10.96665 & \text{ Hourly heat production.}
 \end{aligned}$$

After injection :

$$\begin{aligned}
 V' &= 1529 \text{ litres of air pumped through the large metre.} \\
 t' &= 72.87^\circ - 32^\circ = 40.87^\circ, \text{ number of degrees the air is heated above } 32^\circ. \\
 V + (V \times 40.87 \times .000035) &= 1529 \\
 V + .08317045 V &= 1529 \\
 1.08317045 V &= 1529 \\
 V &= 1529 \\
 \frac{1.08317}{1.08317} &= 1411.819 \\
 W &= V \times .002851, \text{ weight of one litre of air at } 32^\circ \text{ F.} = 4.025. \\
 Q &= 4.025 \times 2.06 \times .2374 = 1.9684 \text{ Heat units taken from the air.} \\
 41.7075 \times .64 &= 26.6928 \text{ Heat units given to the cal.} \\
 1.9684 & \text{ Heat units taken from the air.} \\
 24.7244 & \text{ Hourly heat dissipation.} \\
 (3.26 \times .6 \times .83) &= 1.6234 \text{ Heat taken from reserve.} \\
 23.1010 & \text{ Hourly heat production.}
 \end{aligned}$$

	7.08 +

The plus and minus signs in the first column indicate respectively increase and decrease of heat dissipation and heat production.

The same signs after the heat units expressed indicate (relatively) large and small doses.

Examination of the results as exhibited in Table 2 shows an increase of heat dissipation in seven of the nine experiments and a decrease of heat production in five.

The only deduction that can be made is evident in the table itself, viz., that the antipyretic action of antifebrin is due principally to an increase in heat dissipation aided in more than half the cases by a decrease in the production. Also that, relatively speaking, both large and small doses increase heat dissipation, while as to heat production large doses seem to increase and small doses to diminish it.

Upon examination of the above plate where we have the curves of heat production and heat dissipation so placed as to show their relation to one another, and also to the dose and temperature, it will be observed that an alteration in the normal relation of heat dissipation and heat production occurs in Experiments 5, 6, and 8, where there is an increase of dissipation occurring synchronously with a decrease of heat production instead of a corresponding increase in heat production, since in health increased heat dissipation provokes increased heat production and decreased dissipation decreased production; while, on the other hand, increased heat production is always attended by increased dissipation, and *vice versa*, thus keeping the bodily temperature uniform.

The following experiments were then made to note the relation existing between the temperature and the pulse after the administration of the drug.

Experiment 12.—Rabbit.

Time. P.M.	Pulse.	Press.	Temp.	Remarks.
2.20	100.6°	Canula put in jugular vein.
2.44-45	61	130	Respiration 34.
2.45	68	13003 gramme of antifebrin injected into jugular vein.
2.46	67	122	
2.47	66	130	99.6°	
2.48	69	126	
2.49	66	136	
2.50	67	130	Respiration 36.
2.51	68	130	
2.52	66	134	
2.53	67	128	
2.54	67	136	
3.03	99.4°	Respiration 44.
3.14	99°	Respiration 44.
3.28	98.8°	
3.30	60	114	98°	
3.32	Rabbit killed.

Experiment 13.—Normal rabbit.

Time. P.M.	Pulse.	Press.	Temp.	Remarks.
2.15	97.6°	Respiration 80; temperature before being put on the holder was 103.2°, respiration 56.
2.17.15	50	76	
2.17.45	51	76	
2.18	51	76015 gramme antifebrin injected into jugular.
2.19	50	76	
2.20	52	88	
2.21	...	90	
2.22.15	52	92	
2.25	97.6°	Respiration 48.
2.34	...	100	97.6°	
2.35.15	47	114	
2.37	97.4°	Respiration 38.
2.40.15	53	104	
2.47	96.8°	
2.50	Struggling.
2.51	Tremors.
2.55	Struggling.
3.04	...	106	96.8°	Respiration 34.
3.10	Struggling.
3.15	96.4°	Respiration 30; rabbit killed.

Experiment 14.—Normal rabbit; antifebrin.

Time. P.M.	Pulse.	Press.	Temp.	Remarks.
3.52	102.6°	Respiration 72.
3.54.30	...	114	
3.54.45	68	118	
3.55	71	114027 gramme antifebrin into jugular vein.
3.56	70	120	

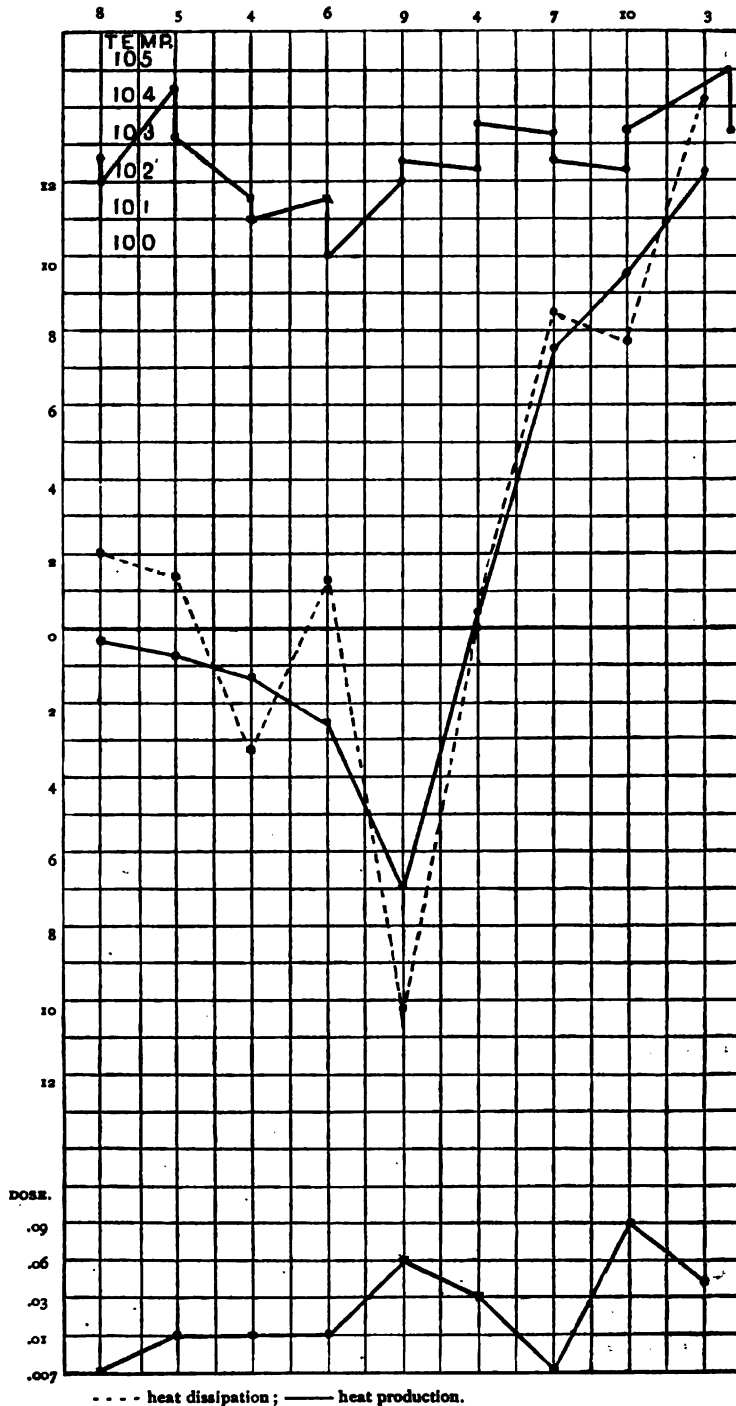

PLATE I.—The dotted line shows heat dissipation and the straight line heat production; the curves above and below the zero line, which is the normal line, mean so many units of increase or decrease of heat production or heat dissipation after the use of the drug.

The dose curve is at the bottom of the plate, while the temperature curve is at the top. Thus, in Experiment 9, the dose is .06 gramme, heat production and heat dissipation are diminished, and the temperature rose from 102.2° to 102.4° .

Time. P.M.	Pulse.	Press.	Temp.	Remarks.
4.05	76	114	102.6°	.075 gramme hypodermically.
4.10	101.6°	Respiration 64.
4.12	...	120015 gramme injected into femoral vein.
4.30	100.6°	Respiration 52.
4.36	...	128	
4.38	69	126	Tremors.
4.54.15	78	120	100.4°	Respiration 56.
5.05	...	118	
5.10	...	120	100.4°	Respiration 44; rabbit killed.

Experiment 15.—Rabbit; antifebrin.

Time. P.M.	Pulse.	Press.	Temp.	Remarks.
2.15	103°	Respiration 32.
2.20	100.4°	After preparation of the jugular.
2.36	100.4°	Respiration 28; tremors.
3.00	99.4°	Respiration 36; tremors.
3.00.15	66	118	
3.01	70	114015 gramme injected into jugular.
3.01.30	72	114015 gramme into jugular.
3.02.30	67	116	
3.03.30	...	12003 gramme into jugular.
3.10.45	60	96	99.8°	Respiration 40.
3.23	...	96	99.4°	Respiration 22.
3.35	...	100	
3.41	100°	Breathing irregular.
3.48	...	102	
3.51	57	90	
4.00	99.4°	Respiration 32; rabbit killed.

The increased heat dissipation observed in a majority of these experiments is evidently not due to a fall of blood-pressure, since the pressure seems to rise instead.

The temperature reduction is also not caused by a fall of blood-pressure, because the facts are to the contrary.

Hence the increased heat dissipation must be due to causes other than circulatory disturbance.

Clinically the drug has been found to increase the pressure and slow the pulse, but this is always in fever, where Müller* asserts the antipyretic effect rarely fails to follow its administration, appearing at the end of the first hour, attaining its maximum at the end of the third, and sometimes persisting for ten hours.

In all my experiments where doses were employed relatively equivalent to those which have given such satisfactory results clinically the temperature invariably fell, the smallest reduction being .4°, while in one case (Experiment 6) it was 1.6°, and this in the normal animal.

Certainly a most favorable indication of its possible action in fever.

The truth or falsity of this will, however, be demonstrated in a future study of its effect upon the fevered animal.

ERGOTINE IN INTERMITTENT FEVER.

DR. S. L. SAVITSKI, writing in the *Vratch* on the value of ergotone in the treatment of intermittent fever, remarks that the drug has been used with success in the treatment of many affections,—e.g., by Vidal in prolapsus recti, by Hunt and Pepper in diabetes, by Saunders, Murrell, and Noakes in diabetes insipidus, by Allan for the cough in some lung-affections, by Granzio in obstinate constipation, by Gauldmel in the night-sweats of phthisis, by De Martini in spermatorrhœa, by Demange in some forms of typhoid fever, and by Girma in general paralysis. It has been also employed in chorea and in dysentery. The theory of its action in these diseases he does not pretend to expound, but he calls attention to the similarity of the action of quinine and ergotone. Both, he says, undoubtedly cause contraction of the uterus and the spleen, the effect of quinine on the uterus having been scientifically worked out in a dissertation published by T. T. Smolski in 1876, and that of ergotone on the spleen having been shown by Dobodchiki (*Vratch*, 1880) and by Semchenko (*Vratch*, 1883). This similarity led him to think that one of these drugs might serve as a substitute for the other, and he therefore made a large number of observations on the effect of ergotone upon the cases of intermittent fever occurring in the Lubinski regiment with excellent results, especially where an enlarged and tender spleen was present. He finds that a combination of ergotone with quinine acts very satisfactorily, and that in this way considerable quantities of quinine can be saved, as half the dose of quinine which would be required if given alone will suffice if combined with ergotone. The preparation of ergotone used was Bonjean's, the dose in chronic cases being about a grain three times a day.—*Lancet*, February 19, 1887.

Leading Articles.

SALOL AS AN ANTIRHEUMATIC AND ANTISEPTIC.

WE have already several times referred to salol as an antiseptic and valuable antirheumatic remedy. As our readers will recollect, this substance is a white powder, without taste, and of an aromatic odor, which may be made by substituting one atom of hydrogen of salicylic acid by the radical phenyl. The substance has recently been subjected to careful study by Drs. Bielschowsky, Rosenberg, and Feilchenfeld, whose papers are published in the second number of *Therapeutische Monatshefte*, a new therapeutic journal, edited by Liebreich. Dr. Bielschowsky reports nineteen cases of acute rheumatism, fourteen of which he designates as especially severe, most of them implicating several joints, and in all of which cure resulted. In eight cases the disease returned, but again was cured by a repetition of the administration of salol, smaller quantities now being required than at first. The disease returned in nearly half the cases cured by this remedy. The number of cases are so small, it is perhaps not to be concluded that a recurrence of rheumatism after treat-

ment with salol is to be dreaded any more than when any other drugs are used. The same author also reports six cases of chronic rheumatism in which the drug appeared to produce no improvement.

Dr. Rosenberg's experience, although he publishes no details, is also favorable to the employment of this remedy. He states that from twenty-four to forty-eight hours only is required in the absolute reduction of fever and pain; the longest time elapsing before relief was obtained occurring in a single case on the fifth day. Dr. Rosenberg also found that in many of his cases recurrence took place in spite of the continuation of small doses of salol. He believes that recurrence of the rheumatic affection more frequently follows the use of salol than with the old treatment by salicylic acid.

Salol should be given in capsules, since it is insoluble in water, although soluble in alcohol. Seventy-five grains may be given in the commencement of a case of acute rheumatism, 15 grains being given every two hours; as soon as fever and pain are relieved the dose may be reduced as low as 30 grains a day, still, however, being given in doses of 15 grains.

It would appear that salol is not entirely free from certain drawbacks, since Dr. Bielschowsky noted four cases in which the action of the heart was slightly disturbed, disappearing, however, on the cessation of the administration of the drug, while in Dr. Rosenberg's experience its administration was powerless to prevent numerous complications of rheumatism, and he refers to several cases in which peri- and endocarditis and pleurisy complicated the affection. Occasionally salol, as is the case in the old salicylic treatment of rheumatism, produces ringing in the ears, sweating, nausea, and vomiting, the sweating being, however, less marked than after the use of salicylates. These unfavorable actions are said to occur in almost all cases, although, of course, in different degrees. Salol when pushed leads to the production of a dark green color in the urine, as in carbolic acid poisoning, which is supposed to be due to the splitting up of salol under the influence of the pancreatic ferments, and its elimination through the urine as salts of salicylic acid and sulpho-phenol. The production of this decomposition in the intestine will explain its value as a powerful disinfectant in intestinal affections, as well as its employment as an external dressing as a substitute for iodoform in the treatment of wounds.

It would appear, therefore, that salol acts as an antirheumatic simply through the salicylic acid which it sets free. It is, however, to be preferred to the latter, being equally efficacious, from the fact that irritation of the gastric mucous membrane is entirely avoided through the use of salol, which is insoluble in gastric juice, and, as mentioned, only breaks up in the small intestine into salicylic acid and phenol. Dr. Feilchenfeld especially calls attention to the use of salol in the treatment of vesical catarrh and pyelitis by its administration internally in doses of 15 to 45 grains. In his experience the employment of salol in all cases of catarrh of the bladder was accompanied by good results, the urine losing its alkalinity and becoming acid, and suppuration being reduced. This favorable action was observed in several cases where other means failed. He also refers to a number of other affections, especially of sluggish ulcers, where its employment was followed by very successful results.

Mr. A. Norman Tate, in a paper read before the Liverpool Chemists' Association on February 3, 1887 (*Pharmaceutical Record*, March 15, 1887), refers to the use of salol as an antiseptic, and believes it in this connection to be very efficacious and much superior to salicylic acid and the salicylates, and he anticipates very satisfactory results after longer trial. As an antiseptic agent it may be mentioned that one use suggested for it is for impregnating bandages or wool for surgical dressings, as it adheres more readily than salicylic acid.

Its preparation has been patented in Germany, England, and other countries, the number of the English patent being 8018, 1886, and it is stated that it may be prepared as follows: 1. Heating salicylic acid and phenol or naphthol with phosphorus pentachloride or phosphorus oxychloride. 2. Melting the sodium or other metallic compounds of the salicylic acid and phenol or naphthol together, with phosphorus pentachloride and phosphorus oxychloride. 3. Treating with phosphorus pentachloride or phosphorus oxychloride the crude product of the reaction obtained in the manufacture of salicylic acid; and, as Mr. Levenstein points out, this last method is probably the most likely to produce the most economical results. The formula of salol, or salicylic phenol ether, or phenol salicylate, is given as

If phenol is replaced by resorcinol, resorcinol salicylic ether may be obtained.

As an antiseptic it may be mentioned that it has neither caustic nor irritating properties, and this is an advantage over some antiseptics now largely employed.

Its special properties have been variously attributed, as, for example, to the phenol it contains, and to the special combination of that substance and salicylic acid, and the liberation of both within the system.

Judging from samples Mr. Tate has examined, he concludes that salol, as supplied commercially, contains about thirty-six per cent. of phenyl.

IS DRUMINE A LOCAL ANÆSTHETIC?

IN a recent issue we referred to an account of some experiments by Dr. John Reid, of South Australia, in which he claimed to have discovered a new local anæsthetic which he termed drumine. As we at that time stated, we did not regard Dr. Reid's experiments as sufficiently accurate to prove the truth of his statements, and unfortunately some recent experiments with the same agent by Prof. Alexander Ogston (*British Medical Journal*, February 26, 1887) appear to confirm our views as to the unreliability of Dr. Reid's statements.

Dr. Ogston received the specimens which he experimented with directly from Dr. Reid. He tested it by injecting 4 minims of a four per cent. solution hypodermically into two persons who were to be operated on, but failed to obtain the slightest anæsthetic results. He also experimented on himself and on a medical student, and found, likewise, that there was no anæsthesia produced, but a tolerably severe pain, which lasted for several days and then disappeared. He then increased the dose to 6 minims, and again found that there was no anæsthesia, but a sharp, aching pain, followed by an area of firm swelling and tenderness over a spot of the size of a crown piece, a result not produced by the alcohol used in the making of the solution when employed alone. The site of the injection remained tender and swollen for weeks.

It was also employed by Mr. Ogston by instillation into the conjunctiva in a number of cases, and produced no anæsthesia, and had no perceptible action upon the pupil or accommodation.

These experiments seem to indicate pretty clearly that drumine as a local anæsthetic has little if any effect, and certainly cannot be compared with cocaine. It is, however, possible

that the specimens with which Mr. Ogden experimented may have undergone decomposition from their voyage from the antipodes. Nevertheless, until the subject has been investigated by a thorough chemist and some one familiar with the methods of pharmacological investigation, we cannot look to find a rival of cocaine in Dr. Reid's Australian anæsthetic.

A SUBSTITUTE FOR MASSAGE.

THE importance of massage in the treatment of various local and constitutional conditions becomes daily more generally recognized. Ten years ago the procedure was scarcely practised in this country, although almost from time immemorial it has been used in Oriental lands. Before the recent changes in the government and laws of Japan its practice was confined by law to the blind, who were thus enabled to make a livelihood in a manner for which they are especially fitted by the peculiar development of the touch-sense which is so apt to follow loss of vision in early life. Provided with a sort of flageolet, the sightless masseur still gropes his way along the streets and lanes of Japan, tooting his instrument to give notice of his presence. In this country we have never known of a blind person practising the art, and we are rather surprised that the managers of blind asylums have never had their attention called to this possible avenue for labor open to their pupils.

Massage acts chiefly by influencing the local circulation in the part which is labored with. The chief objection to it is the skill which is required for its practice and the expense which it therefore entails, and more especially the difficulties of finding employment for its votaries, which forbid its use away from considerable centres of population.

As an aid to or possible substitute for massage, we can strongly recommend the muscle-beaters made by Mr. John G. Ruebsam, of Washington. They consist essentially of india-rubber tubes or balls, so arranged on elastic sticks as to simulate more or less closely the hand as employed in the beating movements of massage. They undoubtedly have the power of distinctly affecting the local circulation in the part beaten with them, and produce no pain or bruising. For the maintenance of nutrition in paralyzed limbs, for the warming of cold feet and other portions of the body which suffer from lack of

circulation, as in neurasthenia, for the stimulation of muscles affected with chronic rheumatism, as in chronic lumbagos, we have found them serviceable. When it is possible to obtain skilled massage, and the severity of the symptoms is sufficient to warrant its employment, the muscle-beater may be very well used once a day as an assistant, so to speak, to the skilled attendant. Thus, in the evening it may be employed to aid the massage and manipulation of the morning.

TREE CULTURE.

BETWEEN the years of 1871 and 1878 the Acclimatization Society of Victoria published five contributions from the pen of Baron Ferd. von Mueller concerning such industrial plants as are available for cultivation in extra-tropical countries or in high mountain regions within the tropics. These contributions became the bases of publications in Victoria, in India, in New South Wales, and in Germany, and finally bore fruit in the present volume before us.* This is a work of nearly five hundred pages full of information concerning all kinds of plants, from the mushroom up, which may be suitable for cultivation in the United States. The work, of course, appeals to the agriculturist rather than to the physician, but we have deemed it proper to call the attention of our readers to the book, that such of them as are interested in the material prosperity of the country districts of America may in turn spread the information of its existence among those who may more directly apply its information to practical life. The scientific standing of Baron Ferd. von Mueller gives great authority to everything that he says.

A NEW THERAPEUTIC JOURNAL.

ALTHOUGH the German literature of experimental therapeutics has during the last few decades been worthy of our commendation, hitherto there has not been any German medical periodical of the first class devoted exclusively to the subject of practical and scientific therapeutics. We therefore welcome to our editorial table very warmly

*"Select Extra-Tropical Plants, readily Eligible for Industrial Culture or Naturalization." By Baron Ferd. von Mueller. Detroit, Mich.: George S. Davis, 1884.

the *Therapeutische Monatshefte*, edited by Dr. Oscar Liebrich and published by Julius Springer, of Berlin, the first two numbers of which we have found of great interest both from a scientific and practical view. The periodical is a monthly one, each number containing about eighty pages.

Reports on Therapeutic Progress.

SUTURE OF THE MEDIAN NERVE TEN WEEKS AFTER DIVISION, WITH RECOVERY OF FUNCTION.

At a recent meeting of the Royal Medical and Chirurgical Society Mr. J. BLAND SUTTON read a paper containing the details of the case of a porter, who, through the bursting of a soda-water bottle, sustained a deep wound of the wrist. The median nerve had been completely divided, and the parts supplied by it were deprived of motion and sensation below the point of section. Ten weeks after the accident the ends were found by dissection, the cut ends vivified and united by suture. Sensation began to return in five days. The most important feature in the case was the ease with which the ends of the severed nerve were found by following the rules which had been gained by studying the effects of neurotomy in horses. A list of previous cases of secondary nerve-suture accompanied the paper.

MR. HOWARD MARSH said he felt much obliged to the author of the paper, for the subject was an important one, and the operation comparatively recent. He had seen several cases, and estimated the results as uncertain.

MR. HOLMES remarked that Mr. Sutton seemed to set much value on the knowledge he had gained from neurotomy in horses, where he had observed a cord running from one end of the divided nerve to the other, and serving as a guide in the search for the other end so soon as one is found. He could not think that any such guide was to be found in most cases in the human subject, especially when there had been any laceration about the division of the nerve, or any suppuration round it. He regarded the operation as common, the benefit as uncertain, but he should certainly recommend it if the nerve-ends could be found; in fact, in such a case he should think the operation urgent. In his own practice he had had a remarkable case, where the nerve had been divided six or seven months; the ends were then sewed together, and though

there was no improvement in function for the next three or four months after union, there was ultimately complete recovery. His colleague, Mr. Pick, had had a case in a boy, in which after nerve-suture there was no immediate improvement, and the boy was sent away from the hospital as a case of complete failure. After the long suspension of recovery which had been noticed in the other case it was thought worth while to make further inquiries after the boy, and these showed that he also had recovered completely after a long interval. The best prospects for the operation were that the injury should have been both simple and recent.—*British Medical Journal*, January 15, 1887.

A NEW REMEDY FOR ITCHING PILES.

R Tinct. capsicum, 1 part;
Spts. turpentine, 2 parts;
Spts. camphor, 3 parts;
Decolorized iodine, 3 parts. M.

SALOL IN ARTICULAR RHEUMATISM.

An address on salol and its employment in articular rheumatism and other acute febrile diseases was delivered before the Berlin Medical Society on January 10 by DR. HERRLICH (*Medical Press*, February 9, 1887). He first referred to the investigations made by Nencki and Sahli into its composition and therapeutical effects. According to these observers it is a salicylate of phenic ether, resembling fat in its behavior in the system in being decomposed by the pancreatic ferments into free acid and alcohol,—salicylic acid and phenol. Salol is a colorless crystalline body, with a weak aromatic odor, is almost tasteless, and practically insoluble in water. It never produces nausea, like salicylate of sodium, and is more readily taken. Sahli treated nearly all the cases of articular rheumatism in the poliklinik with it in daily doses of 6 to 8 grammes in individual doses of 2 grammes (30 grs.) each. It was always well borne in these doses. A strong salicylic acid reaction was found in the urine two hours after the first dose. There was no fear of carbolic urine appearing after the doses given. The drug contained forty per cent. of phenol and sixty per cent. of salicylic acid. There was no doubt that the antipyretic action was due mainly to the phenol. Singing in the ears was not always avoided, nor were endocarditic complications.

In addition to the good effects in acute and subacute articular rheumatism, a prompt action was observed in several cases of neuralgia in which salicin had proved inert, and also in *erythema nodosum* and *multiforme*, urticaria, and peliosis. In phthisis, Sahli recommends it in doses of only 0.5 gramme ($7\frac{1}{2}$ grs.). It is useful in all cases of diabetes.

Further indications for its employment, on account of the local antiseptic action of both its constituents as set free in the duodenum, were noticed. It is highly probable that it acts antiseptically in the intestinal canal, and it will therefore probably prove useful in intestinal catarrh, typhoid, and cholera.

Syphilitic and other ulcers were rapidly healed by being painted several times a day with salol in powder. It was also found useful in ozæna and otorrhœa, and a three per cent. solution formed an agreeable antiseptic mouth-wash.

Herrlich had used it in twenty-five cases of acute articular rheumatism, in a series of cases of chronic rheumatism, and in some cases of muscular rheumatism, lumbago, etc. It showed itself of decided benefit in the acute form. He could not say what part the carbolic acid played. In any case, the action was so rapid and striking that six grammes of salicylic acid did not correspond to it, so that it might be assumed that the carbolic acid played a part in the rapid improvement. Relapses and endocarditic complications were uninfluenced by it.

PHOSPHATIC DIABETES.

At a meeting of the Medical Society of London, held January 10, 1887, DR. RALFE brought forward a case of phosphatic diabetes, and read the particulars of twelve others (*British Medical Journal*, January 15, 1887). These he arranged in groups, in which excessive elimination of phosphoric acid occurred in connection (1) with derangement of the nervous system; (2) in relation to pulmonary disease; (3) as alternating with diabetes mellitus; (4) as running a distinct course like saccharine diabetes, only without sugar. The cases occurred mostly in young male adults, the chief features being great and progressive emaciation, thirst, increased appetite, a tendency to boils, cataract, a dense urine, with or without increase of the other urinary constituents, but always an exaggerated excretion of phosphoric acid. The causes that led to this increased elimination of phosphoric acid were not definitely determined; probably two

factors were concerned, namely, inability of the tissues to utilize the phosphorus brought to them, and also an excessive formation of acid in the tissues dissolving out the earthy salts. The prognosis in cases associated with derangement of the nervous system or with pulmonary disease was very gloomy; on the other hand, it was a favorable sign when in diabetes mellitus the sugar was replaced by phosphoric acid. Out of three cases related, two had completely recovered, whilst the third was running a very mild course. With regard to the term phosphatic diabetes, it was evident that the increased elimination of phosphoric acid was symptomatic and not a disease *per se*; it would be improper, therefore, to use the term in that sense, but it would be useful as a distinctive appellation to distinguish between phosphaturia, caused by deposition from alkaline urine, but without excess, and the enormous discharge of phosphoric acid, met with in urines, but not necessarily deposited from them.

VASELINE IN THE HYPODERMIC INJECTION OF ANTISEPTICS.

MEUNIER, of Lyons, considers vaseline as diffusing itself very rapidly through all the tissues of the body; its diffusibility varies inversely with its consistence, which may be that of a perfect liquid or that of wax; it preserves its diffusibility when holding in solution a microbicide. Antiseptics dissolved in vaseline, when injected beneath the skin or applied upon a wound or a mucous surface, are diffused without exciting pain or reaction, provided that the substances used be pure and in doses which can be tolerated; the dose and consistence of the dissolvent must be varied according to the organ treated.

The method of treatment is as follows:

Among the antiseptics used in these experiments upon animals were carbon bisulphide, carbolic acid, camphor, creasote, salol, chloride of camphor, iodoform, thymol, essence of cubebs, oil of santal, copaiba, oil of cinnamon, turpentine, thyme, eucalyptus, mint, koussou, and most of the vegetable alkaloids. After these solutions had been tried successfully upon animals, they were employed upon men. These are the formulæ:

Eucalyptol (pure), 5 parts;

Chemically pure vaseline, 20 parts by weight.

The injections are made upon the outer side of the thigh. The dose tolerated varied

from 15 minims to $3\frac{3}{4}$ drachms and more, daily.

Eucalyptol (pure), $\mathfrak{m}\text{xxv}$;
Iodoform, $\mathfrak{m}\text{iv}$;
Vaseline (pure), $\mathfrak{z}\text{v}$.

The dose tolerated is the same as for the first mixture.

Carbon bisulphide, $\mathfrak{m}\text{xxv}$;
Vaseline (pure), $\mathfrak{z}\text{iv}\frac{3}{4}$.

Of this mixture, 15 to 30 minims, and more, can be given daily, provided small doses are used.

Turpentine, pure (prepared after the method of Berthelot), $\mathfrak{m}\text{xxv}$;
Vaseline (pure), $\mathfrak{z}\text{v}$.

From $\mathfrak{m}\text{xxv}$ to $\mathfrak{z}\text{iiss}$ may be given daily.

It is of the utmost importance that these substances should be chemically pure, and that they be given with the greatest accuracy in measuring the doses.

All impure vaselines turn black in contact with sulphuric acid. Most samples of commercial vaseline give the following reaction :

When saturated with the purest carbolic acid and slowly heated, it becomes rose-colored, but deposits a violet precipitate. The intensity of the violet color of the precipitate increases on the addition of alcohol ; and the color, which is probably aniline in its nature, indicates the presence of nitrogenous impurities which are dangerous ; the abundance of the precipitate is in proportion to the amount of impurity present.

In every test made pure vaseline did not give these reactions, and also gave no pain or reaction when injected into animals.

Among antiseptics the essences are nearly all impure. For example, commercial essence of eucalyptus has a strong odor, an acrid taste, an acid reaction, and boils at 80° ; its active principle, eucalyptol, which boils at 175° (Cloëz), forms only a third or a half of the commercial article. The same is true of turpentine and its essential element, and of other substances mentioned. Almost all essences contain resins which should not be introduced into the economy. When these articles are mixed with pure vaseline these resins are precipitated, and may be separated by filtration. Pure eucalyptol is not precipitated by vaseline. To prepare for injection, these antiseptics should be thoroughly shaken with the pure vaseline, allowed to stand, and filtered through two Berzélius filter-papers.

Experiments upon animals with these solutions were made in the treatment of the fol-

lowing diseases : fistulous, fungous, tuberculous, and cystic tracts ; favus, herpes tonsurans, alopecia, psoriasis, eczema, acne, and venereal lesions ; albugo, granular eyelids, glaucoma ; puerperal fever.

Animals were also treated for anthrax, scab, farcy, and tuberculosis, general and local.

In all the trials made albuminuria was never produced, even when a temperature of 104° F. was reached and large doses were given. Among many interesting and important observations made was the injection into the lung of a horse of $\mathfrak{z}\text{v}$ of a solution of eucalyptol, $\mathfrak{z}\text{v}$ of a solution of bisulphide of carbon, without unfavorable reaction ; 10 drops of eucalyptol solution were injected into the eye and windpipe of a rabbit ; 15 drops into the eye of a sheep ; $\mathfrak{z}\text{iiss}$ under the skin of a horse. Pure vaseline was injected in the following heroic doses under the skin of a horse weighing eight hundred pounds :

First injection, $\mathfrak{z}\text{viiss}$.

Second injection, $\mathfrak{z}\text{xiv}$ four hours after the first.

Third injection, $\mathfrak{z}\text{ix}$ ten hours after the second.

In all, one kilogramme (about two and one-fifth pounds) in twenty-four hours.

The whole was well borne by the animal ; more could have been tolerated ; the best point of injection was at the animal's side ; diffusion was instantaneous when the point of injection was rubbed with the hand.

Regarding the use of impure vaseline, a case is cited in which the injection of $\mathfrak{m}\text{xxv}$ of impure vaseline, injected into the arm, resulted in phlegmon and the formation of a pint of pus. These solutions are also appropriate for the making of antiseptic dressings, and the surgeon can thus make for each case the appropriate dressing, as the circumstances of the case indicate.—*Bulletin Général de Thérapeutique*, January 15, 1887.

DECOMPOSITION OF ANTIFEBRIN IN THE BODY.

WENDRINER, in the *Centralblatt für Medicinischen Wissenschaften*, No. 8, 1887, describes the following tests for antifebrin : If a small quantity of antifebrin be added to normal urine, and the fluid be made strongly alkaline with caustic soda and distilled, aniline is found in the distillate. The urine of patients who have taken antifebrin, however, gives no such reaction for aniline, but antifebrin is decomposed in the organism. Such urine, when

distilled with an acid, gives a considerable amount of phenol, whereas in urine of those who are not taking antifebrin but a faint trace is present. The quantity of the phenol eliminated is about five and one-half per cent. of the antifebrin taken.

THE TREATMENT OF MALARIAL DISEASES BY PICRATE OF AMMONIUM.

Picrate of ammonium possesses valuable therapeutical properties, though it does not seem to have received the attention it deserves. Its properties and uses were first investigated by Dr. Dujardin-Beaumetz in 1872, but it now appears to have passed out of mind. In the *Lancet* for February 19, 1887, MR. H. MARTYN CLARK, of the Amritsar Medical Mission in India, states that his attention was attracted to it accidentally in the following way. He had a patient under his care who had suffered for several months from severe intermittent fever of the quotidian type. Quinine, arsenic, and other antiperiodics had been used freely, but without relief, and after ten days' treatment the fever still recurred daily with its accustomed severity. At this time the local chemist told him of a remedy for fever which he had received some years previous, but had never employed it. This Mr. Clark found to be the picrate of ammonium, and he gave it to his patient with very gratifying results. The fever did not recur the next day nor at any time during the three subsequent months in which the patient remained under observation. Mr. Clark states that he has since then used the picrate of ammonium in the treatment of malarial diseases during a period of four and a half years. He claims that he has treated over ten thousand cases with this agent with the happiest results. So uniformly successful has it been that he has practically given up the use of quinine and cinchona alkaloids in the treatment of intermittent fever, and he has substituted picrate of ammonium for them. The record was kept of five thousand cases of this fever treated with this agent. Of this number, in nine cases only did it fail to cure, and in these quinine succeeded at once.

He usually gives it in doses of from $\frac{1}{8}$ grain to $1\frac{1}{2}$ grains four times a day in pill; $\frac{1}{2}$ grain is a fair average dose. Thus given the result is soon visible. In the cases treated, $\frac{1}{2}$ -grain doses in the interval prevented the recurrence of the next attack of the fever, while in about twenty per cent. of the patients two or three attacks followed before the fever ceased. In

one case of quartan ague, despite large doses of the salt, the fever recurred for six periods, gradually diminishing in intensity, and then yielded to it. It is equally successful in all the forms of ague, but it is a curious fact that the cases in which it failed to cure were all of the tertian variety. He has also employed this agent in the treatment of twenty-five cases of malarial neuralgia of various nerves, six cases of malarial headache, and one of malarial colic. In all these instances it cured completely and speedily. In remittent fever it does not appear to be of use; six cases of a severe type were treated with it without any effect. Neither is the enlarged spleen of ague benefited by it. Mr. Clark has given it in numbers of such cases in conjunction with ergotine with good results, but such results are secured equally by the use of the ergotine alone.

The writer's experience leads to the conclusion that in all varieties of intermittent fever, and in malarial neuralgias, picrate of ammonia is a valuable antiperiodic, and it is an efficient and perfect substitute for quinine. It has the following advantages over quinine:

1. It is much less expensive. This is an important consideration where, as in Indian practice, hundreds of cases of malarial diseases have to be treated annually.
2. The dose given is very much smaller.
3. It does not produce the unpleasant effects that quinine does,—headache, deafness, tinnitus, etc.,—nor does it disorder the digestion or cause nausea, as quinine is apt to do, in the doses in which it has to be given in India.

THE TREATMENT OF HÆMOPTYSIS BY ATROPINE.

HAUSMANN, of Meran, in discussing the above subject, cites the dictum of Traube, that the successful treatment of hæmoptysis consists in the formation of a thrombus in the vessel chiefly concerned, a result best accomplished by lessening the force of the blood stream and also the lumen of the vessel. Although in capillary hemorrhage it is impossible to make smaller the aperture from which blood is escaping, we can endeavor to lessen the calibre of the arterioles, and thus diminish the force of the current of blood in the capillaries. This lessening of blood-pressure may be aided by restricted diet, ice, absolute quiet, digitalis, and agents acting upon the vasomotor nerves by an astringent or reflex action. Traube mentions as a list of hæmostatic agents digitalis, acetate of lead, alum,

tannic acid, the astringent preparations of iron, and several mixtures, as Chopart's. The first agents of this list Traube would use in inflammatory conditions; the second portion would be used against severe hemorrhage. He advises that if no effect is produced by one agent it be promptly replaced by another; and advises morphine injections for pain or mental disturbance.

Ergotin and oil of turpentine have been added to the number of drugs used, but unimportant hemorrhages have been best treated by dietetic means and by rest. Sée employs preparations of turpentine, terpine, ergot, and, as a last resort, morphine subcutaneously and alcohol. The writer has given wine with good results in bleeding from passive venous congestion, and recommended exercise and deep breathing as remedial agents; while in active bleeding, rest, ice, and morphine have been found of great value. It is often the case, however, that all remedies are unavailing, and daily hemorrhages persist.

Too energetic treatment is naturally not indicated. Patients often bear medicines badly, and the physician is forced to have recourse to the oldest modes of treatment,—binding the lower extremities; the application to the genitalia or inner surface of the thigh of cold compresses in rapid succession; cold compresses also applied to the chest and over the shoulders, which resulted in some instances in pressure upon the subclavian vein. All of these means, however, often proved useless.

In doubtful cases the writer has seen remarkably good results follow the use of subcutaneous injections of atropine, of which it is possible here to give but a few examples. In one case, which presented cavities in both apices, and had two dangerous hemorrhages daily for six days without a check, three physicians were present at the thirteenth hemorrhage, which was promptly checked by the subcutaneous use of sulphate of atropine in dose of $\frac{1}{100}$ of a grain. The same patient had hemorrhages two months after the first, which were checked by atropine only.

In the case of another patient who, during the winter of 1884, in spite of the best of care at San Remo, had suffered for months from pulmonary hemorrhage, which had ceased in summer, only to recur on the winter following for a long time, two hypodermic injections of atropine sulphate, in doses of $\frac{1}{100}$ of a grain, cured the hæmoptysis completely.

At the close of October the writer saw a pulmonary hemorrhage of severity in the case of a lady who had been treated for eight days

with injections of ergotin and with turpentine, etc., quickly checked by subcutaneous injections of atropine in doses ranging from $\frac{1}{100}$ to $\frac{1}{12}$ of a grain, once or more often repeated. —*Therapeutische Monatshefte*, January, 1887.

PEPSIN IN THE TREATMENT OF CHRONIC TROPICAL DIARRHŒA.

In the *Indian Medical Gazette* for December, 1886, MR. GEORGE HARRISON YOUNG reports three cases of chronic diarrhœa which had proved rebellious to the ordinary methods of treatment. In each of these cases the treatment was stopped, and the patient placed on a milk diet, a half-pint being taken every three hours, and 5 grains of pepsin given four times daily. The record of his cases appears to show that great benefit was derived from the use of pepsin. Mr. Young states that he has now used pepsin in a considerable number of cases, and always with success. He claims that this mode of treatment is especially applicable to that form of diarrhœa in which the motions are large and frothy. These cases are due to insufficient digestion and secondary fermentation of the food. When this form of disease becomes established astringents are useless and even often injurious. Pepsin at once checks the diarrhœa. Only milk diet should be allowed, and the pepsin may be given with the milk. In typhoid fever, the author claims that pepsin, by increasing digestion and assimilation of food, will thereby lessen the diarrhœa and intestinal irritation, and by so doing will diminish the severity of the disease. It is also useful in dysentery occurring in debilitated subjects.

CATHETERISM OF THE AIR-PASSAGES.

The introduction of a catheter into the larger air-passages, for the purpose of local medication or mechanical dilatation, or to obviate recourse to tracheotomy, has been much facilitated since the introduction of cocaine into laryngeal surgery. A paper recently read before the Medical Society of the Charité Hospital at Berlin by DR. LANDGRAF, clinical assistant (*Berl. Klin. Woch.*, 1887, No. 5), illustrates the ease with which the procedure is effected. He described a case presenting symptoms of stenosis of the left bronchus; the symptoms, which had gradually increased in severity, dating over two years. When admitted into the hospital last July, the patient was liable to dyspnœal

attacks; and physical examination led to the above diagnosis. The constriction was at first thought to be due to compression, a view which was borne out by the presence of a small area of dulness over the manubrium sterni and to its right. There was no evidence that this was due to a tumor arising in the bronchial glands. The long duration of symptoms negatived the existence of a malignant tumor, and the absence of bacilli in the sputum set aside the notion of tubercular disease. Aortic aneurism was more probable; but this diagnosis lacked confirmation, the only positive sign being the area of dulness. It was, therefore, thought to lie between syphilitic stricture (the patient had contracted syphilis twelve years previously) and aneurism; and, since the former gave a more hopeful prognosis, the patient was placed under anti-syphilitic treatment. But the dyspnoeal attacks increased in frequency, and measurement of the chest showed a diminishing capacity of the lungs. Further, an examination made at the beginning of October revealed what was thought to be a membrane deep down in the trachea. This appearance supporting the endo-bronchial character of the stenosis, it was resolved to resort to catheterism. The larynx was anæsthetized by a twenty per cent. solution of cocaine, and a ten per cent. solution was injected into the trachea. The catheter was easily passed to a distance of 28.5 centimetres from the teeth (found subsequently to correspond to the tracheal bifurcation) without meeting any constriction. The catheterism was repeated at intervals, and on several occasions to a depth of thirty-five centimetres, with a view to traverse the left bronchus. The measure produced so much relief that at the end of the month the patient was well enough to leave the hospital. Unfortunately, the diagnosis of stricture, which had been apparently confirmed by the relief of the symptoms, proved incorrect; for in a few weeks he returned, having had a severe asphyxial seizure, and shortly after died. The cause of the stenosis proved to be—what is by far the most common cause of such a condition—an aneurism of the aorta, which compressed the left bronchus. The condition, which was mistaken during life for a membrane, was an anæmic part of the right wall of the trachea. Although during life some irregularities in the mobility of the vocal cords were observed,—on one occasion the right cord moving less on respiration and phonation, and on another the left cord appearing im-

mobile in the middle line,—yet the dyspnoeal attacks could not be referred to involvement of the vagus. They must have been due to the compression of the bronchus, for they disappeared directly the narrowing produced by that compression was mechanically relieved. Dr. Landgraf fully recognized the danger of resorting to such mechanical dilatation in aneurismal cases, and he would hesitate to catheterize in any case in which aneurism could be suspected. Nor is it quite easy to account for the great relief temporarily afforded by the measure in this case. The valuable point learned from it is the ease with which the air-passages can be catheterized with the aid of cocaine, thus affording means to relieve strictures, as well as to apply remedies locally to ulcerated surfaces on the respiratory tract.—*Lancet*, February 19, 1887.

HYPNONE.

VON SCHÜDER writes of fourteen patients treated by acetophenon, or hypnone, in whom favorable results followed. A dose of from 2 to 4 drops was sufficient to produce sleep of several hours' duration; the effect was especially happy among the phthisical.

No ill after-effects were observed. In one case only, after 6 drops had been given, the patient awoke from a long sleep with headache and slight vomiting. The effect, dependent upon the dose and the individual peculiarities of each patient, was manifested after from one-half to one and one-half hours.—*Der Pharmaceut.*, February 1, 1887.

THE DURATION OF THE SYPHILOGENIC CAPACITY IN RELATION TO MARRIAGE.

At a meeting of the Medical Society of the County of New York held on February 28, 1887, Dr. P. A. MORROW read a paper with the above title, which is especially of interest as showing the most recent beliefs as to the probability of the transmission of syphilis after apparent cure (*Medical Record*, March 5, 1887). Dr. Morrow claimed that the fundamental characteristics of syphilis were two: first, prolonged virulence, and, second, susceptibility to hereditary transmission. What is the duration of the contagious stage of syphilis? A century ago the majority of syphilographers would have answered that it began and ended with the chancre. At the present day it is impossible to fix a definite limit when the syphilitic organism is cleansed

from the contagious element. The author of the paper then directed attention to the results of experimentation, and also to clinical evidence, which he regarded as conclusive that in the late tertiary stage the disease is still contagious. Especial attention was also directed to a paper published by Dr. F. N. Otis, in which the writer had taken a position that was opposed by an overwhelming mass of clinical testimony,—that is, that after the termination of the second year it was impossible for a man, all manifestations of syphilis having disappeared, to communicate syphilis. Dr. Morrow believed that the doctrine of the paternal transmission of syphilis was supported by most authorities on general medicine, and also by most syphilographers.

He concluded that there was nothing constant in contagion, and nothing certain in heredity; that the modern division of syphilis into secondary and tertiary periods did not furnish a safe criterion concerning the contagious or the non-contagious character of the lesions; that the chronological completion of the secondary stage did not mark the definite disappearance of the virulent principle; that in the immense majority of cases the contagious activity of syphilis, and its susceptibility of hereditary transmission, ceased after three or four years, but there were well-authenticated cases in which it manifested itself as far removed as five or six years, and even later; that the precise date, in the evolution of the diathesis, when the limit of its contagious or transmissive power had been reached, did not admit of mathematical expression; that this limit was materially influenced by the type of the syphilis, the character of the treatment, the presence or absence of certain conditions, etc., and that to fix the date at which a syphilitic man could marry with safety at three or four years, with or without treatment, and irrespective of the existence of specific lesions, was unwarranted by science or the teachings of experience.

The discussion was opened by Dr. F. N. OTIS, who maintained that all the processes of syphilis were processes of growth, characterized by cell-proliferation non-inflammatory in character, and that when the contagious element had been removed the disease was at an end; that beyond the secondary period of syphilis, however long that may be proved to be present, there was no contagion; that all the lesions of the tertiary period of syphilis were free from the contagious element, and were simply sequelæ of the disease; that the period at the end of which marriage could

take place with safety had, after thorough treatment, been fixed by the profession throughout the world as three or four years; that there should be, after thorough and prolonged treatment, an interval of a year or eighteen months, during which, without treatment, no syphilitic manifestation had appeared. These were statements in which all believed. For himself, he believed that the person was beyond the contagious stage of the disease at the end of three years, if proper treatment had been carried out. He claimed that, in view of the enormous mass of evidence presented, and of the general experience of authorities, wherever syphilis had been communicated at a period later than three or four years, it would be shown, in such cases, that the true source of the disease was in a lesion less than three years old.

TESTS FOR KAIRIN AND ANTIPYRIN.

KOHN gives, in the *Chemische Zeitung*, the following tests:

For kairin. A drop of solution of ferric chloride gives with a dilute watery solution of kairin a violet color, which changes suddenly to brown. An excess of ferric chloride gives a dark brown, and a concentrated solution a brownish-black precipitate.

Potassium bichromate gives with a neutral solution of kairin at first a dark color, from which a violet coloring-matter very soon forms, which gives with alcohol a mauve-colored solution.

Antipyrin gives with ferric chloride a red color, which is formed with very dilute solutions. Solutions of antipyrin give with nitric acid a clear, greenish-blue color; concentrated solutions deposit greenish crystals. This test reacts in dilutions of 1 in 10,000.

THE ACTION OF ACONITE UPON BODILY TEMPERATURE.

DRS. LAUDER BRUNTON and J. THEODORE CASH have, in a research upon the action of aconite upon bodily temperature ("St. Bartholomew Hospital Reports," vol. xxii.), reached the following conclusions:

1. That in pigeons aconite acts as an antipyretic, both in large and small doses.
2. This antipyretic action is exerted whether their body temperature be normal, or be artificially raised, or artificially reduced, at the time of the injection of the drug. In all

cases the injection causes the temperature to fall.

3. This fall is usually less in birds which have been artificially cooled than in birds whose temperature is normal, or has been raised artificially.

4. The action of the drug is apt to be modified by individual peculiarities in the birds which we are at present unable to explain.

5. The temperature returns more rapidly and completely towards the normal when the birds which have got aconite are kept in a warm place, although the primary fall induced by the administration of the drug may have been as great as, or greater than, that observed at medium temperatures.

6. A repetition of the dose after the effect of the first one has passed off causes a fall which is apparently uninfluenced by the first dose.

7. It is occasionally noticed that a large dose may cause a fall of temperature which is smaller but more prolonged than that caused by a smaller dose.

8. In guinea-pigs cooling appears to retard the fall of temperature caused by the drug, and also to retard the return to the normal.

9. The temperature of animals exposed to a heated atmosphere is but little affected by aconite; in fact, large doses may diminish the resistance of the animal to the effect of external heat, and cause the temperature of an animal to rise higher than that of one to which no aconite has been given.

10. If the animal be exposed to cold when the drug is administered, the fall of temperature is both more rapid and more extensive than in the normal animal.

THE TREATMENT OF COLDS.

DR. J. H. WHELAN states in the *Practitioner* for March, 1887, that he has found a combination of belladonna, quinine, and arsenic almost specific in aborting common colds if commenced in the early stage of the affection, while it is still confined to the nose and pharynx. The formula which he uses is the following:

R Quininae sulphatis, gr. xviii;
Liquoris arsenicalis, ℥xii;
Liquoris atropinae, ℥i;
Extracti gentianae, gr. xx;
Pulveris gummi acaciae, q.s. ut fiant pilulae xii.

Sig.—One every three, four, or six hours, according to circumstances.

Dr. Whelan states that at starting one pill

should be taken every three or four hours, and later on every six hours, and he believes that if a catarrhal subject has a box of these pills always at hand he will almost invariably succeed in aborting a cold.

He does not profess to explain how his remedy acts, unless it be as a powerful nerve and general tonic.

THE USE OF HYDRASTIS CANADENSIS.

FELLNER orders the fluid extract as follows:

R Ext. hydrastis fluid.,
Vini malagæ, aa ʒviiss;
Syrupi cinnamom., ʒxi. M.

Sig.—A teaspoonful or half-tablespoonful every four hours.

The alkaloids berberine and hydrastine are of similar action, and of these Fellner recommends berberine phosphate and hydrastine hydrochlorate as most soluble, in the following formulæ:

R Berberini phosphorici, gr. xv;
Dissolve in boiling water ʒv, and add
Vini malagæ,
Syrupi cinnamom., aa ʒiv.
Sig.—20 to 30 drops every two to four hours.

Also

R Hydrastine hydrochlorat., gr. xv;
Dissolve in distilled, boiling water, ʒiiss, and add
Aq. aurant. flor.,
Syrup. toltutan., or
Syrup. menthae pip., aa ʒiv.
Sig.—15 to 25 drops every two to four hours.

—*Therapeutische Monatshefte*, January, 1887.

THE TREATMENT OF EMPYEMA WITH PULMONARY GANGRENE BY PERFLATION.

At a meeting of the Royal Medical and Chirurgical Society, held in London, March 8, 1887, DR. WM. EWART and MR. R. FITZROY BENHAM read an account of a case of "Empyema with Pulmonary Gangrene following Enteric Fever treated by Perflation" (*Lancet*, March 12, 1887). The patient, a male, aged 10 years and 11 months, was seized with enteric fever (due, probably, to drain infection) on April 23, 1886. The symptoms were not unusual in character, but severe in degree, especially the delirium. The treatment adopted by Mr. Benham consisted of quinine, which proved ineffectual, and of antipyrin, which appeared to relieve the pyrexia and the delirium. The

patient was convalescing at the end of the fourth week, when peritonitis supervened, soon followed by left pleuritic pain. Within a week the signs of left empyema were fully developed, the exhaustion was extreme, and the dyspnoea bordered on asphyxia. On June 11 aspiration was made, and three-quarters of a pint of thick, shreddy pus removed, with relief of the most urgent symptoms. The following day the chest was opened freely in the anterior axillary line (fifth space), and in the scapular (ninth space), a large quantity of pus escaping. Free discharge continued, but no injection was used. On June 15 perfusion was performed under spray, in the manner depicted in the *Lancet* (July 31, 1886), the appliances being elastic tubing, a Wolfe's bottle containing carbolic acid solution (1 to 10), and a hand-ball bellows. The air was delivered into the centre of the chest through the anterior opening, and allowed to escape only at the posterior. The result was the expulsion of fetid pus, of a piece of necrosed lung, and of heavy false membranes. A smaller mass of membrane was expelled by perfusion the next morning, and a small piece on the third day. From this day the fetor ceased, and the amount of pus decreased rapidly. On the eighth day the discharge was turbid-serous, and it remained serous to the end. Both wounds were closed on the thirtieth day from the date of incision, and on the twenty-fourth from the first perfusion. Among the advantages obtained in this case by the method employed were the following: 1. Early removal from the chest of putrid residues. 2. Presumably considerable shortening of the period of suppuration as a result of 1. 3. Avoidance of permanent atelectasis and of eventual resection of ribs as a result of 2. 4. Avoidance of deformity as a result of 3. 5. Daily dressings, free from discomfort and from wet (excepting the spray). 6. A dryer state of the cavity and of its coverings than is allowed by fluid injections, with absolute sweetness of the discharge.

The PRESIDENT asked what was the advantage of perfusion over free incision at the most dependent part, with, if necessary, excision of the rib.

SIR DYCE DUCKWORTH believed the practice of washing out the pleura was a mischievous one. He would use perfusion in future in that class of cases where, having made a free opening with antiseptic precautions, the patient did not progress satisfactorily.

MR. GODLEE thought the case peculiar, in

that a piece of gangrenous lung was discharged without a history of previous fetid expectoration. He considered that a free opening posteriorly without perfusion would have met the needs of the case. Injecting the pleura was a mode of treatment now passing out of fashion. In cases requiring it he recommended blowing iodoform into the pleural cavity with an insufflator.

MR. BENNETT inquired what was the result of treatment in adults and in those cases which, previous to its use, had not done well. He could not recommend its adoption in general surgery, for in one case in which he perfused an abscess in the thigh he produced extensive subcutaneous emphysema.

MR. R. W. PARKER had published a paper in the Society's Transactions many years ago advocating a similar method to this. He had abandoned injection, and made a single large opening, into which a double drainage-tube was passed.

DR. DAWTREY DREWITT likened perfusion to the school-boy practice of "blowing" an egg, and pointed out the difficulty of separating the inner membrane from the shell by that method.

MR. HOWARD MARSH said he adopted the following method of evacuating an empyema: First make an opening high up; from this pass a catheter and feel the lowest part of the pleura; then make a large opening at this lower point, and allow the upper one to close. He believed washing out the cavity was not advisable, and, indeed, unnecessary. He objected to the insufflation of iodoform, which, he thought, might act as a poison. In excising a rib, if the periosteum were left, deformity would be avoided.

DR. SANSOM said the air would not be sufficiently purified by being blown through water. He advocated passing the warmed air over blotting-paper, cotton-wool, or sponge, saturated with pure carbolic acid.

MR. PEARCE GOULD thought the value of the method could scarcely be judged from one favorable case. He considered the best treatment was a single free opening in the sixth or seventh interspace and in the post-axillary line.

DR. EWART, in reply, agreed as to the value of a large opening. He believed perfusion useful in recent empyema to discover whether loose pieces were present. In older cases it might be beneficial by effecting the removal of an irritant. He had treated five cases of left-sided empyema, and perfusion in them had produced no effect on the heart.

In using this method in general surgery, care should be taken to have free openings, so as to avoid undue pressure.

THE ABSORPTION AND ASSIMILATION OF FOOD-STUFFS.

HOFMEISTER, of the German University of Prague, in a series of reports of work done in the Prague Institute of Pharmacology, writes as follows upon this subject :

Experiments upon animals which consume flesh have shown that a portion of their food is quickly assimilated through the agency of the mucous membrane of the intestine and stomach ; and that as factors chiefly concerned in this assimilation are the epithelium of the gastro-intestinal tract and the cellular connective tissue, rich in lymph-cells. Following up his histological studies, Hofmeister has sought to determine whether changes in relative nutrition are attended by morphological changes in the mucous membrane, and whether such changes may not throw light upon the structure and nature of the elements composing these mucous membranes. The free absorption of certain materials by cells renders, under favorable circumstances, the cells and their contents visible ; this occurs with glycogen and fat. This process may result either in a great enlargement of cell-volume or in greatly increasing the number of cells. In the first case, microscopic examination would afford a demonstration of the conditions present. The recognition of an increased number of cells can with certainty be early accomplished ; the caution should always be borne in mind to avoid confounding increased cell-formation of normal glandular elements with the development of elements introduced from without.

Change in the Number of Lymph-Cells in the Intestinal Mucous Membrane under the Influence of Nutrition.—The experiments reported were performed upon cats. Two animals of equal age, growth, and nutrition were chosen, one of which was fed liberally with meat, the other was starved for several days. When time had elapsed for the assimilation of the food taken, the animals were killed, and portions of the digestive tract were hardened in alcohol. Slides were made of sections prepared, and the pylorus, duodenum, middle and extremity of the small intestine, appendix vermiformis, and large intestine were examined. The intestines of a number of cats in various stages of fasting and repletion were

examined, pairs of animals and single ones being used for comparison, and osmic acid preparations were made. The result of these experiments was that fasting produced no effect upon the number of cells in the mucous membrane proper, while a manifest effect was readily observed upon the number of cells in the lymphatic connective tissue. This lymphatic tissue is much richer in cells in animals well fed than in those starving ; and further studies have shown that this condition does not depend upon a temporary repletion, but upon the general condition of the animal's nutrition.

Differences in the number of cells in the lymphatic tissue are readily recognized where well- and poorly-nourished animals are compared, especially if the latter be fasting. They are easily recognized and plainly discernible when animals of equally good general nutrition are compared, of which one is in full digestion, the other hungry. These differences are not, however, to be observed with certainty when a well-nourished, but fasting, animal is compared with a poorly-nourished animal which has recently been abundantly fed. It is then hard to determine which is the predominant element in the result,—the temporary digestive repletion or condition of generally good nutrition.

Nutritive changes in the digestive tract are not equally apparent in all portions of its extent. The influence of digestion during the period of absorption is most plainly seen in the stomach and upper portion of the small intestine, while the influence of a general condition of nutrition is equally marked in all portions of the intestine.

The appearances of different portions of the digestive tract are, briefly, as follows :

In the stomach the subglandular lymphatic connective tissue in hungry animals is much smaller and poorer in cells than in those in full digestion. The fibrous tissue, which forms the basement membrane of the lymphoid tissue, in animals in full digestion is often covered with cells ; in fasting animals it is plainly visible. The lymph-follicles in such animals are, when present, small, wasted, flattened against the mucous membrane, and the number of their cells greatly lessened ; the follicles of animals in digestion are wide, oval, or bullet-shaped, and distended with cells. The tissue about the follicles, in digesting animals, is also rich in cells, and the lymph-channels likewise.

Small Intestine.—The differences in the contents of the adenoid tissue in animals fasting

and digesting, which is greatest in the upper portion of the intestine, shows itself most plainly in the abundance or lack of cells in the parenchyma of the intestinal villi, the subvillous and interglandular tissue, and, to a less extent, in the subglandular connective tissue. In fully fed animals the villi are broader, the glands of Lieberkühn distended with cells, the subvillous spaces crowded with cells. In fasting animals the villi are shorter or smaller, poorer in cells; the glands lying closely together, the subvillous spaces appear trabeculated, containing few cells, and these appearances are the more marked the longer the condition of hunger exists; these conditions are most readily seen on the surface or by cross-section of the mucous membranes. In the duodenum the solitary lymph-follicles were prominent in only two animals, and as these animals were in full digestion, comparison with fasting animals was impossible.

In the jejunum and ileum the influence of nutrition was most manifest in the lymphatics of Peyer's patches. After abstinence of several days they are plainly visible. In well-nourished animals during digestion the follicles stand closely together, raised above the surface of the mucous membrane, and easily recognizable. In fasting animals they are sunk into the submucous tissue, scarcely recognizable above the mucous membrane. On removing the superjacent tissues, so that the under surface of a plaque is exposed, if the animal be in full digestion, a grayish, glistening tissue is seen, which, when punctured, extrudes an abundance of milky fluid, clear and rich in cells. In fasting animals the contracted follicles are separated from each other by a white boundary substance, so that the plaque has the appearance of a net-work. On perforating such a plaque a watery fluid which contains but few cells is procured with difficulty.

On microscopic examination it is found that the changes observed in fasting animals depend upon a marked diminution in the number of cells contained in the follicles. Each individual portion of the gland was small, collapsed, cell-infiltration failed, the spaces between the segments of the cells were wide and showed trabeculae of connective tissue; the villi shared also in this depletion. The glands of Lieberkühn were perpendicular to the surface of the mucous membrane, while in fully fed animals they are crowded one against another out of the perpendicular. The nutritive changes in the large intestine were like those of the small intestine; owing

to the smaller amount of lymphoid tissue present they occur less frequently. By prolonged fasting it is difficult to recognize a diminution in lymph-cells, especially in the follicles of the appendix vermiformis. The fact of the increase in the number of cells in the adenoid tissue of the intestines may be explained upon two hypotheses,—that of the extravasation of leucocytes from the vessels during increased circulation; the segmentation of living protoplasm in the cells of the tissues.

If the first hypothesis were true, the largest number of cells would be found near the blood-vessels; this, however, is not the case. Further, the lymph cells within and without the blood-vessels should have the same structure if they are the result of extravasation; the cells contained in the capillaries and small vessels are multinuclear; while it is rare to find cells in the adenoid tissue of the intestine which are not uninuclear. It is possible also that the multinuclear cells did not escape from the blood as such, but that they were originally extravasated and formed as uninuclear cells.

Flemming has demonstrated the generation by proliferation of lymph-cells in the plaques of Peyer and in the large intestine; Hofmeister has observed the same phenomenon,—has counted as many as seventy cells in a single section, and so distributed that it is doubtful if a "centre of generation" was present. The single follicles of the stomach and small intestine showed the same germination, and confirmed the improbability of the existence of centres of generation; the lymph-channels were also filled with cells. The presence of such numbers of cells in those portions of the intestine which contain the follicles must depend either upon the accession of a great number from without, or the proliferation of cells independently of the follicles. It is highly improbable that these numbers of cells have been extravasated from blood-vessels or from the follicles, although the vicinity of Peyer's patches is always rich in cells: the facts indicate that in the mucous membrane of the intestine cells proliferate abundantly outside of the follicles, as the following observations show:

To avoid errors, safranin, gentian, or hæmatoxylin should be used as stains; care should be taken in sections cut obliquely through Peyer's plaques when it is difficult to distinguish free lymph-cells from those of the neighboring glands.

It is probable that nuclei of mother-cells

divide and separate themselves from the original protoplasm, forming in the process figures of various kinds observed in the crypts of the interglandular tissues. The fact that this process less often results in wandering lymph-cells leads to caution in their recognition outside of the follicles. It is, however, possible in thin sections to recognize clearly a large number of germinating cells in the lymphoid tissue wherever cell-infiltration is most pronounced. In the stomachs of well-nourished cats extra-follicular lymph-cells were found between and beneath the glands: the number was greatest near the pylorus. In the small intestine cells were found in the parenchyma of the villi and in the subvillous and interglandular tissue, but so poorly developed in the subglandular tissue as to be scarcely noticeable. They were found most frequently in the periphery of the connective tissue about the villi. The fact that karyokinesis occurs in the adenoid connective tissue of the intestine makes it unnecessary to suppose that the new cells so formed have their origin outside the intestine. The experiments narrated were repeated upon dogs, which showed a greater inter- and subglandular infiltration than in cats.

The conclusion reached by these experiments was that the autochthonous cell-development of the adenoid connective tissue of the intestines is greater than that of any other portion of the body.

The foregoing observations, however, point to this cell-proliferation as one of the assimilative functions of the intestine. They also prove that the process described is a proliferation of cells independent of lymphatics, as is shown by the difference in essential characteristics between the cells of the glands and the lymphoid cells. The writer has seen such cells in pure fibrillated connective tissue, in interglandular lymph-spaces, and mixed with blood-corpuscles in the capillaries at the bases of the villi. These lymph-cells are independent in their growth of all surroundings except their nourishing medium. Remembering that the tissues of the digestive tract draw their nutriment directly from the products of assimilation, the karyokinesis of lymph-cells appears as the morphological result of a series of chemical and assimilative processes, which culminates in the new organization of the cell. This conclusion is verified by the fact that these cells are present in great numbers among the epithelium of Lieberkühn's crypts; they are less abundant in the stomach, and still less abundant in the large

intestine. Whether imputed to development for a specific object in the economy, or as a result of physiological processes, it is not difficult to understand.

The epithelia of the absorbing portion of the intestine are best situated for the consumption of its contents; in the second place are the lymph-cells of the adenoid tissue.

It is not alone in the intestines that lymph-cells assimilate nutritious matter; the mesentery and its lymph-follicles furnish a multitude of dépôts where such activities go on. The intestine and mesentery together may be considered one large tubular lymphatic gland, the various parts of which have essentially the same function.

Flemming has shown that the mesentery absorbs nutrient matter and proliferates cells. The fact that lymph passes through chains of glands before reaching the blood explains the apparent riddle that absorbed material is found in the blood which is not present in the thoracic duct; each gland is capable of absorption and direct assimilation and transference to the blood.

The exact way in which this mesentery and intestinal gland apparatus performs its function we do not know; that it has an important bearing on the nourishment of the individual we cannot doubt.

The experiments just described show that the increase in lymph-cells is independent of the glands themselves, but is an assimilative function of the intestine; these leucocytes have been found in the trabeculae of connective tissue, and mixed with white and red blood-corpuscles at the capillaries in the bases of the villi. These cells depend for their growth and nutrition, not upon the neighboring tissues, but upon the fluid or serum which circulates about them.

Inasmuch as the cells in question take no part in the composition of the blood and lymph, it is evident that these fluids contain in but small degree those elements upon which karyokinesis depends. When we consider that the difference between the interstitial lymph of the connective tissue of the digestive mucous tract and the fluid of the lacteals consists in the most recent products of digestion, and that the number of cells in the intestine sustains a relation to nutrition not fully determined, we are led to the conclusion that not only the increase in the number of nuclei and amount of cell-substance, but also karyokinesis itself, are direct products of digestion. Karyokinesis of lymph-cells appears, then, from this stand-point to be the

morphological and discernible result of a series of chemical and assimilative processes. The final act of this assimilation is the new organization of the cell.

With the above an observation already noted fully agrees. The lymph-cells which have been described are most abundant at Peyer's plaques, less frequently found in the gastric submucosa, and rarely present in considerable numbers in the tissues of the large intestine. The writer has repeated the work of Heidenhain, and found that the great increase in the lymph, whether existing for a definite end or as the result of a physiological plethora, is easily explained by reference to the condition of nutrition. The epithelia of the absorbing portion of the intestinal tract are most favorably situated for absorbing nutrient matter; next after them are the lymph-cells of the adenoid connective tissue.

The adenoid connective tissue is only, however, the first halting-place at which lymph-channels come into relationship with nutrient material. That which is not appropriated follows the lymph-currents to the mesenteric glands. These bodies are so situated as to intercept the lymph which passes from the intestines to the thoracic duct. In suckling animals, along the bases of the mesentery the lymph-channels converge in such a manner that it is evident that a special mechanism is here constructed for the reception of nutrient matter, both finely divided and dissolved. The lymphoid connective tissue and the mesenteric glands seem to be portions of the same apparatus, having the same function.

Flemming has already shown that an abundant proliferation of cells occurs in the mesenteric glands. It is not, however, possible to carry out the analogy with the lymphoid tissue of the intestine, and show that *pari passu* with cell-proliferation nutritious matter disappears. It is evident that the lymph-channels afford greater obstacles to the general diffusion of nutritious matter than do the blood-vessels, non-diffusible fat, for example, passing through the lymph-channels, and it is somewhat enigmatical that certain products of digestion, as peptone, are often found in the blood and never in the chyle of the thoracic duct.

When we consider, however, that products of digestion must pass through a chain of lymph-glands, which retain such matter, and apply it to the production of new cells, these phenomena are more intelligible. In the light of such investigations, the great lymph apparatus of the intestine and peritoneum

seems to be especially adapted for the most useful and economical assignment of nutritious matter, acting, as it does, as an intra-cellular transport. The precise method of this action we do not, as yet, know. Its importance to the bodily economy may be inferred when we consider the value, in the body, of the numberless cells contained in the intestines and their glands.

Regarding the function of the peripheral lymph-glands there are two theories worthy of attention. One of these theories depends upon the facts observed regarding the dependence of the numbers of cells upon digestion and nutrition. We should then ask whether, inasmuch as the nutritive changes in the adenoid connective tissue coincide closely with the period of digestion, this cell-proliferation is to be regarded as the result of the increment of nutritious matter? Should not the full development of nutritive processes result in a much more widely-spread diminution in the number of cells than we have just observed? A closer observation shows the proposed coincidence between digestion and cell-growth when it arose from introduction of lymph-cells from without, or the extravasation of leucocytes from the blood. Lymph-cells are plainly formed in the place and situation where nutrition goes on, but no such coincidence as that mentioned can occur, for the reason that cell-proliferation and karyokinesis persists for hours after absorption of nutritious matter. In this wise also it happens that the mucous membrane of the intestines for days after the last ingestion of food contains unassimilated matter in small quantities, and is thus in a position to continue proliferation. It is not surprising that, after an abstinence of a day or two, the contents of the adenoid connective tissue are only partially depleted of lymph-cells. With the disappearance of ingested nutritive matter from the intestine the assimilation and absorption of nutritive matter does not cease, but it happens, to make use of a comparison, material brought fit for the mint is coined and put into circulation again and again. It is evident that such an arrangement provides for the nutrition of the tissues in the pauses in the reception of nutrient matter. To ascertain to what extent abstinence influences cell-proliferation the experiment was made of subjecting an animal to hunger for fourteen days; there results a general lessening in the number of lymphoid cells, but even an abstinence of seventeen days, producing inanition, did not entirely remove them. Through still longer

continued hunger the mucous membrane of the intestine lost an amount of cell elements, which reduced the volume of the villi and glands to two-thirds, and lessened the circumference of the bowel. The infiltration with lymph-cells sustained a considerable loss, which fell more upon stationary lymph-cells than upon those merely formed in the connective tissue. The actual loss in the constituents of the follicles was a relative one and not absolute; it was seen in cross-sections of the tissues, and also in counting the cells extruded in the fluid from the follicles. The atrophy of the follicles may be so great that, in comparison with the newly-formed lymph-cells, the cells of the follicles may disappear entirely, and even the cells remaining may show a diminished circumference and a smaller amount of coloring element. The statement that the formation of lymph-cells does not depend entirely upon nutrition leads to the following considerations: if the adenoid connective tissue, including the peritoneal glands, receives a portion of the nutritious matter, what portion should be allowed that numerous lymphatic array, which, like the peripheral lymph-glands, are not enriched by nutrient matter in the intestinal lymph? The answer to this question is in full accord with what has been said. It can happen that a portion of digested matter enters the blood and disappears first in the capillaries of various organs. If the quantity of peptone resulting from digestion is too great for ready assimilation, or the adenoid connective tissues already overstocked, a portion of the peptone may enter the venous circulation unchanged, and be sent from the heart through the organism; it can also happen that the tissues may transfer non-assimilated peptones to the efferent lymphatics, and this peptone, on its way to the general circulation, may be intercepted by lymphatic glands, where it is retained and assimilated, as happens in the intestinal and mesenteric glands.

What has been said of peptone absorbed in the intestine is true of other substances which behave similarly.

In accordance with the great diversity in the arrangement of the tissues, as well as by their functional differences, it will scarcely be credited, as that which is half unknown so often happens, that from the waste of active cells, as well as excrementitious matter from the blood, the chemical changes follow after the same rules, and invariably bring it to pass that at the location and place of the cell are produced the final products of cell-activity,

—carbonic acid, urea, and water. There are also many intermediate products of decomposition in greater or lesser amounts, which if not wanted at one portion of the body may be useful at another. Schmiedeberg, Bunge, Waldemar von Schröder, Mirkoraski, and Max von Frey have shown that the transition of these substances into excreta does not always occur in the same amounts, but more often at certain regions of the body which seem designed for this purpose. The products of decomposition, when they find no acceptance where they were produced, enter the stream and reach the lymphatic glands, and there undergo a process which renders them fit for the production of new cells. What is not accomplished at the lymphatic stations takes place in the blood, and at every station where an excretory product is developed. From this stand-point there is no necessity for the peripheral lymphatics to differ in function from the mesenteric; their function is different only in this, that they do not draw from the contents of the intestine, but gain their nourishment from the excess and overflow of other organs. During prolonged periods of digestion quantitative experiments may be done in part. The lymph apparatus of the intestines during hunger takes its nutrition from the residue of the intestinal wall, and is in this degree comparable to a normally-acting peripheral lymph-gland.

It is, therefore, not remarkable when the new formation of lymph-cells does not entirely cease in these lymphatics; and hence there is room for doubt whether the passage of nutrient material from the intestine is ever absolutely in suspense during hunger, although it may sustain a great reduction.

Many anatomical and pathological facts indicate that many lymph-glands always or occasionally assume important but different functions. Especially interesting is the development of adenoid connective tissue in mucous membranes not designed for absorption; the explanation of these facts demands further investigation.—*Archiv für Experimentelle Pathologie*, February 8, 1887.

INDICATIONS FOR THE USE OF NITRO-GLYCERIN.

DR. TRUSSEWITSCH, in an instructive paper on the use of nitro-glycerin published in the *St. Petersburger Medicinische Wochenschrift*, points out that the value of this drug in various affections—angina pectoris, migraine, and neuralgia (which he describes as angio-

neuroses), as also in sea-sickness, some forms of anæmia, faintness, palpitation, and other diseases—depends upon the existence of an irregular distribution of blood, which condition may be inferred from a certain degree of pallor of the skin, especially of the face, often coexistent with a weak pulse and a small rigid radial artery, which frequently is situated at some depth. When, on the other hand, headache and neuralgia occur in patients with chronic congestion of the subcutaneous veins of the face, nitro-glycerin is to be avoided; and similarly it is of no use in asthma, when the face is reddened in consequence of emphysema. If, however, a pale face exists with angina pectoris, migraine, giddiness, shock, toothache, or sea-sickness, the best results may be looked for by giving nitro-glycerin. The regulating effect of the drug exercises an influence over the congestion of internal organs similar to that brought about by blood-letting; and in these congestions, whether of lung, brain, or kidney, when they are of a temporary character, the pulse is generally found to be slow and of low tension,—a fact which, as the author remarks, is sufficiently well known in reference to the fever-free periods of acute hyperæmia of the lung and kidney. Dr. Trussewitsch lays down as a rule that the condition of the pulse is the best indication for the employment of nitro-glycerin, and the most trustworthy guide as to the dose with which to commence the treatment. The smaller the radial artery is, the more rapidly it dilates under the action of the drug, and the less the secondary effects proceed; on the other hand, the fuller the pulse with a distended radial artery, the less it is affected; and, finally, the softer the artery with a weak pulse, the greater the secondary and the less the general effects. Single-drop doses of the one per cent. solution are sufficient in cases of small pulse, but with a full pulse it will be found that the full effects cannot be produced with less than 2-drop doses. When there is a soft artery with a weak pulse, sub-normal doses only should be given,—a quarter to half a drop. After the trial dose is given, the patient's sensations of pulsation and pain in the head, as well as the distention of the radial artery under the finger of the physician, will be the guides for increasing the dose. The author finds that the best modes of administering nitro-glycerin are the simple dropping of the solution on the tongue and by means of tablets; much less satisfactory results were obtained when given mixed with water.—*Lancet*, February 19, 1887.

TESTS FOR ANTIFEBRIN.

Yvon has employed the following tests: Good specimens of antifebrin must be white or pale yellow in color and odorless. To detect the presence of a trace of unchanged aniline, which is poisonous in its effects, a little antifebrin is rubbed up with water, and sodium hydrobromide added. If the specimen is pure, the fluid remains clear and yellowish in color. If aniline is present, an abundant, reddish-orange precipitate is formed, and the supernatant fluid has a like color.

A reaction, which proves the identity of antifebrin, consists in heating it with mercuronitrate, when a green coloring-matter forms, soluble in alcohol. The same reaction may be applied to the examination of urine by shaking the urine with chloroform, and heating the solid residue with mercuronitrate. This test shows even traces of antifebrin.—*Pharmaceutische Zeitung*, March, 1887.

THE PROGNOSIS IN CASES OF HEART-DISEASE.

In the *British Medical Journal* for February 12 and 19, 1887, SIR ANDREW CLARK reports a long series of cases of valvular diseases of the heart known to have existed over five years without causing serious symptoms, from a study of which he draws the following conclusions:

"1. That there are many persons with long-standing valvular disease of the heart, engaged in the active business of life, who without any symptom of heart-disorder have enjoyed good health and have reached an advanced age.

"2. That the mitral regurgitant murmurs so often encountered in chorea, for the most part disappear within eight or nine years of the attack.

"3. That valvular inflammations, and their effects arising in the course of rheumatic fever, do sometimes disappear, and leave behind no clinical evidence of their former existence; and that this occurring for the most part in the young, also occurs sometimes in the middle-aged.

"4. That the signs of valvular defects arising out of the degenerative changes of middle life do also, on rare occasions, disappear, and that, when circulatory and respiratory disturbances accompany their commencement, they sometimes subside, and permit of apparently complete readjustment.

"5. That as there must be in the histories, habits, occupations, and surroundings of patients with valvular disease conditions

which in one case bring about secondary disorders, and in another case exempt it from them, it is desirable that the respective *differentiæ* should be discovered and made capable of application to practice.

"6. That any systematic and critical study of this subject likely to lead to practical issues could be undertaken only by the Collective Investigation Committee, and not by it unless actively assisted by experienced general practitioners who possess, in a special manner, the knowledge necessary to the end in view.

"7. That a joint inquiry of the kind proposed, conducted with due patience, discrimination, and accuracy, would greatly extend our knowledge of the natural history of diseases of the heart, and largely increase our means of assisting those who suffer from them."

IODIDE OF SODIUM.

Iodide of sodium is considered by DR. RICHARDSON as a valuable substitute for, or adjunct to, iodide of potassium. In chronic eczema and painful rheumatic affections it often answers well when iodide of potassium does not agree with the digestion. Combined with arsenic it is useful in lepra and psoriasis. Externally applied, in cases of indolent ulcer, chronic syphilitic sores, and offensive discharges from the nostrils, it acts as a good antiseptic. The following is given as a useful formula for the purpose: Sodium iodide, ʒss; tincture of myrrh, ʒi; rectified spirit, ʒii; distilled water, ʒvi. To make a solution of eight ounces. Used in the form of fine spray from Seigle's steam spray-inhaler, Dr. Richardson found it of the greatest service in a case of syphilitic ulceration of the fauces.—*The Provincial Medical Journal*, March 1, 1887.

SPARTEINE.

DR. GLUZINISKI, in a preliminary note published in the *Przegląd Lekarski*, gives the results of some observations, both physiological and clinical, on the action of sulphate of sparteine. Its main action is to slow the heart; besides this, it raises the blood pressure. On cold-blooded animals it acts with a greater degree of intensity than on mammalia. The action on mammalia may be divided into three periods or stages, during the first and last of which the effects are more marked than during the second. Indeed, in some cases the heart is even quickened during the second period. This may be explained by

the existence of some abnormality or pathological change in the irritability of the vagus or of the heart-muscle. The reflexes are at first increased, afterwards diminished. Death occurs from asphyxia, and is due not only to the effect on the medulla, but to that experienced by the respiratory muscles. The therapeutic use of sparteine is limited to the first stage of its action. Its value consists in the rapidity with which it acts. In some cases, within an hour after the first dose, the pulse begins to improve, as well as the subjective sensations of the patient, and no irregularity is produced. Sparteine has not so powerful an action as digitalis. It may, however, be useful in cases where the condition of the patient renders it inadvisable to wait for the more tardy effect of digitalis, and it may therefore be used as an adjunct to the latter drug, besides which it may be prescribed where circumstances exist which contraindicate the use of digitalis.—*Lancet*, February 19, 1887.

SUCCESSFUL TREATMENT OF HYPERPI- REXIA IN ACUTE RHEUMATISM BY THE COLD BATH.

At a meeting of the Clinical Society of London, held February 25, 1887, DR. CARRINGTON read a paper on the above subject. He said that although there was nothing new in the case he brought forward, still he thought it was well to put such cases on record, in order to accumulate a body of evidence such as would enable medical men to combat the prejudice existing among the friends of patients against the employment of a remedy which afforded the only chance of safety in this desperate complication. The patient was a medical student aged 23, strong and muscular, and hitherto in perfect health. He had been ill with what was apparently a mild attack of rheumatism, for which he had been treated by salicylic acid. He was so far recovered that he had left his bed, and on the evening of October 31 had received the visits of his friends. He passed a good night, and there was nothing to excite attention next day; but on taking his temperature next morning about twelve, noon, quite as a matter of routine, it was found to be 107° F. Dr. Carrington saw him soon afterwards, and then found the temperature to be 106°. He was, as soon as practicable, removed to the private ward of Guy's Hospital, but during the journey had become noisy and delirious, and by the time he had been placed in bed

he was quite livid, unconscious, and generally convulsed. His temperature was then found to be 109.8° . The necessary arrangements had been previously made, and he was at once placed in a bath at a temperature of 70° , which was as rapidly as possible cooled down by ice. Large quantities were used, but the body heat was so great that there was great difficulty in lowering the temperature of the bath. Pouring ice-cold water on the patient's head had a beneficial effect. A rectal injection of 15 grains of antipyrin was administered. He was kept in the bath for a full hour, and when the rectal temperature was 102.4° he was removed and placed on a blanket, and lightly covered by a sheet. Then marked tetanic convulsions supervened, and he gradually became quiet, and at 7 P.M. his temperature fell to 97.2° . At 8 P.M. consciousness returned, and he took a pint of milk, and at 10 P.M. he was quite rational. During the next day he remained comfortable, and took gr. xx of salicylate of sodium every two hours, but his temperature again rose, and at 12 P.M. it was 103.8° . He was given gr. xv of antipyrin by the mouth, but at 2 A.M. the temperature was 105.2° , and the ice-bath was again employed for fifteen minutes. He was taken out when his temperature had fallen to 101° , but at 6 A.M. it had again risen to 105.4° , and the bath was again had recourse to for a similar period. After this he slept well, but at 2 P.M. the temperature had reached 105° , and he was bathed again for forty minutes. From this time the temperature never again rose to any extent; it was for the most part normal, but on one occasion, with a return of the articular pain, it reached 101° . After the third bath, salicin was substituted for sodic salicylate, in 25-grain doses every two hours. After two days he took it every three hours, and the dose was gradually reduced. With an interruption due to the slight relapse, the patient made an uninterrupted recovery, from this time, and left the hospital quite well. The experience of the case seemed to be that within the limits of collapse prolonged immersion was more effectual than shorter and more frequent baths.

DR. HALE WHITE said that the failure of salicylate of sodium and antipyrin was of interest, as leading us to see in some manner the way in which those drugs acted. In rheumatic pyrexia, at any rate, they were not of value. It was possible that it would by and by be discovered that each drug was applicable to a particular class of cases.

The PRESIDENT said that he had not seen convulsions occur during the rise of temperature. He had seen them come on during the cold bath in a case which ultimately proved fatal, and he had seen hyperpyrexia supervene during the use of salicylate of sodium.

DR. HUGHLINGS JACKSON wished to know the exact nature of the convulsions, and particularly whether they were tonic or clonic, or both.

DR. STEPHEN MACKENZIE said he had had three or four cases of hyperpyrexia in private practice, and could endorse the remarks as to the difficulty of the cold-water treatment in private practice. He had succeeded in reducing the temperature to normal, but they had all terminated fatally. Those cases required the most careful supervision. The convulsions were invariably tonic.

The PRESIDENT said the convulsions took the form of opisthotonos, without clonic convulsions.

DR. CARRINGTON said in reply that the convulsions came on after the patient had been removed from the bath. The first bath lasted a good hour, as a great difficulty was experienced in reducing the temperature of the bath. He thought the antipyrin did more harm than good by favoring collapse. The salicylate did not appear to have had much effect either way. He thought antipyrin was a dangerous drug.—*British Medical Journal*, March 5, 1887.

THE PHYSIOLOGICAL ACTION OF SPIGELIA, OR PINKROOT.

Although spigelia has been frequently studied from a clinical point its physiological action has received no attention, and we reproduce, therefore, almost in full the studies made on this subject by DR. H. A. HARE, and published in the *Medical News* for March 12, 1887.

When as much as three ounces of the fluid extract of spigelia is given by the stomach to a large dog weighing forty pounds, the following symptoms appear: Almost immediately after the ingestion of the dose the animal has short and quick expiratory movements, amounting almost to a cough; soon after the pupils become widely dilated, and at the same time very marked internal strabismus asserts itself; the eyes becoming fixed in this position so that they cannot follow any object, such as a pencil, when it is passed from side to side. Constant retching, with no result,

now comes on, the animal standing, and apparently suffering from no sensory or motor palsy. There is no change in gait. Soon after this marked exophthalmia develops itself. The retching having lasted about five minutes, now passes off, and at this time signs of muscular weakness and lack of co-ordination appear; the walk becomes staggering in both fore and hind legs. The respirations now become very rapid, resembling those of a dog after a long, hot run, the tongue hangs from the mouth and is dry and red, and the nose is hot and no longer moist. Muscular power is progressively lost, so that the dog frequently falls when endeavoring to walk, but sensation does not seem to be affected. About this period the animal lies down and passes into deep sleep, which in turn soon passes into coma, and death follows without any movement being made, evidently from a general failure of vital force. The respirations as death approaches become slow, and are finally extinguished consentaneously with cardiac arrest.

In the frog the same symptoms occur as in the higher animal, including the marked exophthalmia and to a less degree the strabismus. The fixation of the eyeball is extreme, and it feels to the finger like a hard knob, which the lid cannot cover. Muscular weakness with dropping of the jaw comes on, and motor power is constantly decreased, until the batrachian lies relaxed and powerless. That the action of the drug in thus destroying motor power is spinal was proved by the following experiments: If the hind legs are protected from the poison by ligation of the abdominal aorta, the palsy is as great as under ordinary circumstances, and reflexes are totally abolished. Further, if the spinal cord be directly galvanized no movements occur in the hind legs; and, lastly, if strychnine be injected into the body, even in large amount, its action is not only slight, but occurs after the lapse of many minutes. That the drug has no action on the motor nerves is proved by the fact that when the poison reaches the efferent nerves, either through the circulation or when directly applied, galvanization of the nerve-trunks causes normal contractions in the tributary muscles, and the sensory nerves likewise escape, for if the drug be applied directly to the nerve and the foot irritated, signs of pain are elicited, and reflex movements occur. Further than this, if the vein in the leg be tied and the drug injected into the limb, thus protecting the spinal cord, reflexes occur on irritation of the drugged foot.

That the palsy is not cerebral is proved by the fact that movements of muscles supplied by the cranial nerves continue long after the movements in the legs have ceased, and by the other experiments already detailed.

The action of the drug on the circulation is as marked as its effects on the nervous system, and on the cardiac muscle it acts as a direct depressant poison, for if it be injected into the jugular vein in such a way as to come suddenly in direct contact with the heart the movements of that viscus almost instantly cease. Further than this, if the excised heart of the frog is dropped into a strong solution of the drug its movements are almost immediately stopped in a condition of diastolic arrest, although the relaxation is not very marked. When a frog receives as much as twenty minims of the extract of *spigelia* the heart is slowed to a considerable extent, as much as ten or fifteen beats per minute, and diastole, while not increased in length, is nevertheless very full and marked. The change from systole to diastole is abnormally rapid, so that the heart in one moment in systole springs with a quick movement to its full diastolic condition. Systole, however, gradually increases on diastole, in much the same manner as in *digitalis*-poisoning, until finally the greater portion of the ventricle fails to dilate, the apex being tilted more and more forward while the ventricular walls are powerfully contracted. As the systolic pauses increase, the diastolic movements decrease in volume, until finally the heart dilates no more than it does normally. At this time the powerful and heretofore spreading systolic contractions seem to lose power and the heart shortly stops all movement in a semi-relaxed state. Experiments on the warm-blooded animal show that on the injection of one drachm, or less, of the drug the action of the heart is very rapidly slowed in its movements, and that this slowing is chiefly due to central inhibitory stimulation is shown by the fact that if the vagi be cut before the drug is given this slowing does not occur, and also if after the drug has slowed the heart the vagi be cut the inhibition no longer remains.

That the fall of arterial pressure produced by this drug is due in great part to the cardiac depression which it produces is proved, since asphyxia will cause a rise in pressure, and that the pressure returns nearly to normal as soon as the heart gets rid of the drug which has been suddenly injected into it. On the respiratory centre the drug seems to have a still more depressing influence,

respiration ceasing some moments before the cardiac arrest.

EUCALYPTOL IN PHTHISIS.

BOUVERET has employed hypodermic injections of eucalyptol in the treatment of phthisis. The daily dose of the antiseptic has varied from $1\frac{1}{2}$ grammes to $2\frac{1}{2}$ grammes. The duration of the treatment has been from fourteen to sixteen days. Sixteen cases of phthisis were treated by this method; six of the number had fever, and the remaining ten were without fever. There was rarely any local disturbance at the site of injection. It was certain that the antiseptic was absorbed; it could be detected in the breath, but not in the urine. Albuminuria was not observed as the result of the treatment. It is very doubtful whether the number of bacilli was altered in any way by the method of treatment. Sweating, as a rule, was diminished. Its chief effect is as a balsamic preparation on the bronchial secretion, which it influences favorably. MM. Perret and Chabbannes have made experiments with the five per cent. solution of eucalyptol, injecting a mixture of it with tuberculous matter under the skin of guinea-pigs. The general conclusion at which they have arrived is to the effect that the antiseptic is utterly insufficient to prevent the activity of the micro-organism that causes artificial tuberculosis.—*Lancet*, February 19, 1887.

DERMATITIS VENENATA CAUSED BY LEUCANTHEMUM VULGARE.

Leucanthemum vulgare is the name of one of our common plants which is known in different localities as white-weed, or field daisy, and is plentiful in New England and the Middle Atlantic States and is spreading rapidly over the entire country.

In the *Boston Medical and Surgical Journal* for March 10, 1887, Dr. James S. Howe calls attention to the fact that this plant is capable of producing in certain persons a marked inflammation of the skin closely similar to that produced by rhus, dogwood, and sumach, and he thinks it is possible that many cases which have been attributed to these latter plants may perhaps have been produced by the field daisy. He reports four cases, himself among the number, in which severe dermatitis was produced.

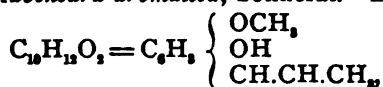

THE SIGNIFICANCE OF THE RETENTION OF THE MEMBRANES AFTER LABOR.

The importance to be attached to the retention in the uterus of portions of membrane after the completion of the third stage of labor has been variously estimated by different obstetricians, some—e.g., Winkel, Dorn, Ahlfeld, and Graefe—holding that grave dangers are to be apprehended when this occurs, while others—as Alshausen, Credé, Fischer, and Cohn (who has reported two cases in which nearly the whole membrane had been retained for five days without causing any pyrexia)—believe that little or no danger of hemorrhage, septicæmia, or other puerperal mischief is caused by the retention of even considerable portions of the membrane. An explanation of this divergence of view has recently been attempted by Professor Lazarevich in the opening article of the new Russian *Obstetrical and Gynecological Journal*. His explanation is founded on the fact, unrecognized by most obstetricians, that "the membranes," even at the full term, are composed of and more or less separable into three distinct layers, representing the chorion, the decidua, and the amnion. The strength of these has been investigated by Poppel, Duncan, and Ribemont, and the amnion shown by them to be much tougher than the chorion in conjunction with the decidua. Professor Lazarevich has also made a number of researches on the subject by means of an apparatus consisting of two rings covered with india-rubber, between which the membrane to be examined was stretched, the resisting force being estimated by means of a wooden hemisphere on which weights were placed, which the membrane was made to support, more weights being added until it gave way. These observations showed that the integrity of the ovum depends almost entirely on the amnion. During labor some separation of the membranes from one another usually occurs; and this is especially the case when the chorion, split or torn below, maintains a close connection with the decidua, and the decidua with the uterine wall. The progress of the labor also separates the amnion from the chorion. Roemer explains the separation of the membranes from one another by their unequal elasticity; and Professor Lazarevich believes that the chorion, being less elastic as well as more easily torn than the amnion, is frequently ruptured in several different places, some portions coming away attached to the amnion, and some being left behind, attached to the uterus. The causes of retention of the chorion

with the decidua are,—1, the presence of villi on the chorion; 2, extravasation of blood on the decidua, with consequent formation of fibrous adhesions; and, 3, adhesions in consequence of endometritis and choriitis. The amnion may be retained in consequence of,—1, occasionally occurring adhesions between it and the chorion and decidua; 2, early rupture and escape of all or part of the liquor amnii; 3, a low attachment of the placenta or placenta prævia; 4, intra-uterine manipulation; 5, anteversion of the uterus after the birth of the child; 6, exceptional weakness or thinness of the amnion. Retention of the decidua (which is formed from the uterine mucous membrane, not from the ovum) is, as a rule, of little moment, though it is perfectly possible for endometritis decidualis to occur, and for the retained portions of the decidua to serve for the development of micro-organisms introduced from without. Shreds of the chorion, if retained either by themselves or together with the decidua, do little harm, as they rapidly undergo chemical and mechanical destruction, and are carried away with the lochia. The amnion, when retained, is much more liable to become the developing ground for bacteria, and it is to the retention of this part of the membranes that alarming symptoms are usually due. Professor Lazarevich lays considerable stress on the importance of straightening or replacing the uterus in its proper position after the birth of the child, before the after-birth comes away.—*The Lancet*, March 12, 1887.

EUGENOL AS AN ANTISEPTIC.

According to GEO. H. OCHSE, Ph.G., eugenol, the principal component of oil of cloves, is found also in *Myrtus pimenta* (*Pimenta officinalis*, Lindley), *Amomis acris*, Berg (*Myrcia acris*, DeCandolle), *Canella alba*, Murray, *Dicypellium caryophyllatum*, Nees, and in *Ravensara aromatica*, Sonnerat. Eugenol,

a phenol-like compound, is insoluble in glycerin and water, and is obtained as residue when oil of cloves is subjected to distillation with strong caustic alkalies. After the so-called light oil of cloves is distilled off, sulphuric or phosphoric acid is added, and by continuing the distillation without access of air eugenol is obtained. Eugenol is an oily, colorless liquid, possessing the odor and taste of oil of cloves in the highest degree. In contact with air

and light it soon acquires a brown color; it boils at 247.5°C ., and has a specific gravity of 1.078 at 0° and 1.063 at 18.5°C . Like phenol, which it resembles very much, it has no acid reaction, does not contain the group COOH , and also forms crystallizable compounds with alkalies. When heated with hydriodic acid it evolves methyl-iodide, and when fused with potassium hydrate it forms protocatechuic acid, $\text{C}_6\text{H}_3(\text{OH})_2\text{COOH}$; with baryta and tin-dust it forms about ten per cent. methyl-eugenol. When taken internally the greater part of it is eliminated by the urine, in which, however, it cannot be detected by its odor nor by distillation, but, if allowed to decompose, the characteristic odor is at once perceptible, and when extracted with alcohol shows the characteristic deep-green coloration with ferric chloride. Eugenol has been given in doses of 3 grammes per day dissolved in alcohol and diluted with water. As an antiseptic, it is superior to phenol; as a febrifuge, it is not as efficacious as quinine, salicylic acid, antipyrin, or thalline.—*American Journal of Pharmacy*, March, 1887.

PNEUMOTOMY IN PULMONARY ABSCESS.

DR. RUNEBERG, Professor of Medicine at Helsingfors, in a clinical lecture which has been published in a Swedish journal published in Finland, gives an account of a case of pulmonary abscess consequent on acute pneumonia, where he had performed pneumotomy with success. In addition to this he had collected notes of ten other cases. Leaving aside three of the eleven on account of uncertainty in the diagnosis, five of the remaining eight recovered, or, at all events, improved very decidedly, and in the rest, which were fatal, death could not in any way be attributed to the operation; so that Dr. Runeberg considers that when the diagnosis of pulmonary abscess is clear, and it is in an accessible situation, the best practice is certainly to open it. He then refers to the question of operating for gangrene of the lung. He himself had had a case of this, together with bronchitis and bronchiectasis. After the operation secondary gangrene and septicæmia occurred, which proved fatal. In seventeen other cases of gangrene he quotes from medical literature where pneumotomy was performed, seven recovered more or less completely, and the fatal termination of the remaining ten did not appear to have been attributable to the surgical interference. As

to the method of opening the lung, Dr. Runeberg is in favor of resecting a rib, and then using the thermo-cautery. He does not approve of washing out the cavity with antiseptic lotions, thinking them dangerous, and believing that ample drainage is sufficient. In conclusion, he mentions several pneumotomy cases he had collected: two were for ecchinococcus, both terminating favorably; six were for bronchiectasic cavities with gangrene; and six for tubercular cavities. In the latter two classes of cases he does not think operative procedures are advisable.—*The Lancet*, February 12, 1887.

FERMENTS IN MILK-JUICES.

A. HANSEN has examined the latex of different species of plants for the presence of ferments. He finds none in the Euphorbiaceæ, in *Ficus elastica*, *Scorzonera*, *Taraxacum*, or the juice of the opium poppy. The latex of *Ficus carica*, on the other hand, contains principles capable of effecting four fermentative changes; they peptonize albuminoids in the presence of either alkalies or acids, act like diastase on starch, and coagulate the casein of milk. Twenty to one hundred grammes of fibrin, previously caused to swell by immersion in hydrochloric acid of 0.2 per cent. strength, are completely dissolved in ten to thirty minutes when treated at 40° with two to three cubic centimetres of this latex. The products of this digestion are the same as with pepsin; yet the two ferments are not identical, since the *Ficus* latex peptonizes in presence of alkalies as well as acids, although more slowly. Probably there are two peptic ferments present, one acting in acid, the other in alkaline, solutions.

By digestion with hydrochloric acid the latex entirely loses its peptonizing properties; digested with sodium carbonate (which destroys the activity of pepsin), it retains them intact. If a few drops of the latex be added to milk, which is then raised to the boiling temperature, the casein is at once precipitated. Incipient ebullition, therefore, does not destroy the curdling power of this latex, although prolonged ebullition does, and even a temperature of 65° if continued for two hours. The diastatic action of this latex is demonstrated by the partial transformation of starch-paste and glycogen into sugar. When the latex is precipitated by alcohol, and the precipitate taken up with water, the action on milk and on starch is found to persist, while that on fibrin disappears.

The latex of *Carica papaya* peptonizes, precipitates casein, and transforms starch into sugar.

The author does not consider that these vegetable ferments play any rôle in the nutrition of the plant.—*American Journal of Pharmacy*, March, 1887.

THE MECHANISM OF THE THIRD STAGE OF LABOR—THE SEPARATION OF THE PLACENTA.

At a meeting of the Obstetrical Society of London, held March 2, 1887, DR. CHAMPNEYS read the first of a series of papers on the above subject, reviewing the facts furnished by our knowledge of the clinical course of natural labor, and by that derived from Porro's operation (*British Medical Journal*, March 19, 1887). From the former it was known that, until the birth of the head, the placenta was not detached, and that after the birth of the head it was not at once detached. Leinser found, by examination of one hundred and sixty-eight women, that the placenta was completely detached as soon as the child was born. As regards Porro's operation, the inferences drawn from it must be regarded with suspicion, on account of the great interference which had taken place with the uterus. The facts derived from these two sources did not tally. He next discussed the theories of the cause of placental detachment: A. By contraction and retraction alone, through reduction of the placental site. B. By contraction and retraction indirectly: (a) by separation of the centre, which was less firmly attached than the edge, leading to aspiration of blood; (b) by squeezing blood towards the surface during contraction; (c) by rapid diminution of intra-uterine pressure, consequent on the birth of the child. C. By detrusion (Leinser), the placenta being forced in the direction of least resistance, namely, the axis of the parturient canal. He then discussed the theories of the modes of placental detachment: A. According to the situation of the placenta. B. From the edge. C. From the centre. D. According to the firmness of attachments of its parts. He then considered the evidence furnished by the various facts, and showed that the question was whether the separation of the placenta was independent of rupture of utero-placental vessels as a cause. The decision depended on (a) proved hemorrhage behind the placenta in normal labor; (b) on the mode of expulsion of the placenta. He concluded that hemor-

rhage to a moderate amount played a certain though subsidiary part in the mechanism of the detachment of the placenta.

METHYLAL.

Methylal is a fluid of specific gravity 0.855; its vapor density is 38°, taking hydrogen as a unit, and a boiling-point of 42° Cent., 107.6° Fahr. Its solubility in blood is one part in three; its composition is $C_4H_8O_2$. It is made by distilling methylic alcohol with sulphuric acid in the presence of peroxide of manganese, but it requires several redistillations before it can be obtained in the pure state, for which reason it is at present a very expensive compound.

When methylal is quite pure it is almost tasteless, but bites the tongue, and, owing to its low boiling-point, quickly evaporates. The odor of it is fragrant, and not very powerful. The pure vapor creates no irritation on being breathed.

After long exposure to the vapor of methylal, in an atmosphere containing not less than thirty-five per cent. of the vapor, warm-blooded animals may be made to pass into a sleep which, once established, is deep and prolonged.

Methylal was first introduced by Dr. B. W. Richardson, who in his early researches supposed that he had found that it was a marked narcotic, but he now states (*The Pharmaceutical Journal and Transactions*, February 19, 1887) that he believes that the narcotism so produced was due to the presence of acetone from the methylal not having been sufficiently pure. Recently, with a perfectly pure specimen, he endeavored to anæsthetize two dogs with methylal in order to enable them to be operated on painlessly. After half an hour's inhalation of the vapor narcotism was not produced. The fluid was then injected hypodermically in one animal and to the extent of an ounce dose, upon which a gentle sleep or rather intoxication followed, but with no sufficient anæsthesia to allow painless operating.

In action as a medicine, methylal lies between alcohol and anhydrous ether. It quickens the action of the heart with reduction of arterial pressure; it makes the respirations slow and deep; it induces a tendency to sleep; and it is a sedative to pain, but not to a very deep degree. On the whole, it would be best to keep it in the group of anodyne antispasmodics, in which Dr. Richardson originally put it. It causes very little muscular excite-

ment and no vomiting, but after long inhalation of its vapor it produces a free flow of saliva. As it mixes well with alcohol and with ether it might be administered with either of these agents, and it might also be given with amyl nitrite for the relief of colic, asthma, angina pectoris, or tetanus; but before it can come into general use it must be reduced in price.

Methylal is very soluble in water, and may be administered by the mouth when diluted with water or by hypodermic injection. Dr. Richardson recommends commencing with a dose of a fluidrachm, mixed either with glycerin or syrup of orange-flowers and distilled water.

THE SIGNIFICANCE OF URIC ACID DEPOSITS IN URINE.

DR. JOHANNES MYGGE, while chief of Professor Trier's clinic in Copenhagen, having repeatedly remarked abundant and persistent deposits of uric acid coinciding or alternating with albuminuria, carried out a series of examinations on the urine of the 272 male patients under his supervision. Of 3287 urines examined, 2786 from 127 patients were entirely free from uric acid deposits, while they were found in 501 specimens from 105 patients, but only in any considerable quantity in 262 specimens from 59 patients. In 43 of these last patients the deposits were of a transitory character,—that is, they were only observed once or twice; while in the remaining 16 they were found to persist for a week or more. Deposits, both of a transient and of a permanent character, were found, especially in rheumatic affections, whether of an acute or chronic form. Transient deposits were found also in pneumonia in 11 cases out of 25. In 27 out of the 59 patients in which uric acid deposits were observed albuminuria was also present in appreciable quantity, and in many of the rest there was a doubtful trace noted. Dr. Mygge's observations confirm Dr. Dickinson's statement that deposits of uric acid of a transitory character frequently coincide with the suppression of acute albuminuria. In the majority of cases where the deposit was examined microscopically, casts or tubal epithelium cells were found, indicating that some connection probably exists between uric acid deposits and functional renal disorder. In some instances, it may be supposed that a peculiar condition of urine, especially its supersaturation by uric acid or an increase in its acidity, has irritated the epithelium of the tubes, and has thus set up a renal lesion.

In others, the latter condition doubtless precedes the precipitation of uric acid, and here Esbach's theory of the precipitation of uric acid being due to the existence of morphological elements in the urine may afford an explanation.—*The Lancet*, February 12, 1887.

ARBUTIN.

Uva ursi leaves contain, in addition to tannic and gallic acids, a bitter glucoside, arbutin, already several times referred to in the GAZETTE, which is white, crystalline, and soluble in water. During the past four years several observers have tried to determine whether arbutin might not, with advantage, be substituted for the various preparations of *uva ursi* now in use. Lewin, in 1883 (*Virchow's Archiv*, xcii. p. 517), showed that arbutin splits up, when boiled with dilute sulphuric acid, into hydrochinon, methyl hydrochinon, and sugar, and stated that when administered it is in part decomposed, so that the urine contains besides arbutin a certain amount of hydrochinon. Now, hydrochinon is itself an antiseptic and antipyretic, and has been found useful by Brieger as an injection in gonorrhœa. Lewin recommended the substitution of arbutin, in 15-grain doses, for the ordinary preparations of *uva ursi*. *Uva ursi* is a reputed diuretic as well as a specific in vesical catarrh. Menche published a paper in 1883 (*Cent. f. Kl. Med.*, xxvii. p. 443) on arbutin as a diuretic, and recorded some cases which served to illustrate its value in cardiac dropsy. Subsequent observations have not confirmed Menche's views on this point. In a few cases of cardiac dropsy, in which the drug was given at the Manchester Infirmary, it proved wholly inefficacious as a diuretic.

Paschkis (*Wien. Med. Presse*, 1884, No. 13) obtained no good results from the use of arbutin in several cases of cystitis and gonorrhœa, though he found these ailments markedly improved by *uva ursi* itself. Either arbutin is not the active curative principle, at least in the doses employed by Paschkis (30 grains daily), or the preparation he used was not arbutin.

Schmiz (*Cent. f. Kl. Med.*, No. 49, 1884) found arbutin very useful in some cases of bladder catarrh. He did not see good results follow its use in all cases, but recommends its use in preference to *uva ursi* itself. Very recently Kunkel (*Munch. Med. Woch.*, December 7, 1886) published his investigations upon the absorption and excretion of arbutin, and has arrived at the conclusion that the

greater part is excreted unchanged; a little is decomposed in the intestine, but it is not decomposed, as Menche thought, in its passage through the system. At the present time, then, the value of arbutin must be regarded as doubtful, and though it may be tried in doses of 10 grains, where ordinary remedies have failed to relieve bladder catarrh, it cannot be used as a reliable remedy. Moreover, its price (about thirty-six cents a drachm) prevents its extensive use.—*Medical Chronicle*, March, 1887.

ANTIPYRETIC ACTION OF NITROGENIZED AIR.

DR. FRANCISCO VALENZUELA, of Madrid, has made some observations (published in *El Siglo Médico*, January 30, 1887) on the effect of inhalations of nitrogen, or rather of air containing an abnormally large proportion of nitrogen, upon febrile diseases. He compared its action in reducing temperature with that of cold applications, quinine, antipyrin, digitalis, and arsenic, and concludes that the inhalation of nitrogen is the only method of treatment the cessation of which for a day is not followed by a rise of temperature to its former height. It has also, he believes, a beneficial effect on the diseased process itself. The plan adopted was to administer the nitrogen in two daily sittings of from half an hour to an hour in duration, beginning with air containing 17.76 per cent. of oxygen, and gradually decreasing this proportion till at the close of the sitting it was reduced to twelve per cent. Some few details are given of a phthisical case in which it was tried. At first some dyspnoea was produced, but the evening temperature at once sank to normal, in addition to which the cough decreased, the blood almost entirely disappeared from the sputum, the sweats became less frequent, and the appetite improved. This patient had been previously treated by quinine, with but little good result. No other cases are reported, though several other patients were treated in this manner, most of whom are stated to have been benefited by it.—*The Lancet*, February 12, 1887.

Reviews.

ON DISORDERS OF DIGESTION; THEIR CONSEQUENCES AND TREATMENT. By T. LAUDER BRUNTON, M.D., D.Sc., F.R.S.

London and New York: Macmillan & Co., 1886.

This is a volume of nearly four hundred pages; the first eighty of which are occupied

with the Lettsomian Lectures, three in number, whose subject is the discussion of imperfect digestion, its results and its treatment. The rest of the work is a reprint of twenty-one papers, which have been previously published, most of them in the *London Practitioner*. No doubt the readers of the *THERAPEUTIC GAZETTE* have become acquainted with the various highly suggestive original articles written by Dr. Lauder Brunton as fast as they have been published, and we shall not occupy space with their discussion, but merely indicate the various subjects. These are Action of Mercury on the Liver—Physiological Researches on the Nature of Cholera—On the Action of Purgative Medicines—Atropine as an Antidote to Poisonous Mushrooms—Physiology of Vomiting and the Action of Anti-Emetics and Emetics—The Physiological Action of Alcohol—On the Action of Alteratives—Symptoms, Pathology, and the Treatment of Albuminuria—Arsenic in Albuminuria—On Dyspepsia—On the Use and Administration of Fats—On the Action of Tonics—Headache and Neuralgia and other Diseases connected with the Teeth—Indigestion as a Cause of Nervous Depression—Introductory Remarks on the Structure and Function of the Kidney—How to make a Poultice—On the Pathology of Dropsy—Pathology and Treatment of Headache—On the Action and Use of Diuretics—On Poisons formed from Food, and their Relation to Biliousness and Diarrhœa.

The Lettsomian Lectures have all the individuality that so plainly marks the work of Dr. Brunton, showing in extraordinary abundance curious out-of-the-way knowledge combined with a peculiarly brilliant suggestiveness and much literary skill. How a good dinner converted the doctor from an enemy of the London "City Companies" to a strong friend is well told on page 19, and shows clearly why these companies are enabled to spend so much money in riotous living and defy the efforts of the Parliamentary committee: for what Parliamentarian could withstand the seducing influence of a dinner whose æsthetic perfection is only comparable with the rare beauty that overspreads the canvas of a Raphael?

Every practitioner of medicine should carefully read these papers of Dr. Brunton at least once, or, if needs be, buy the book for such purpose. We cannot, of course, give the full argument, much less even shadow forth the details, which are, after all, the most valuable portions of the book. For the purpose, how-

ever, of affording a peep into this treasure-mine, we call attention to the way in which it is shown that the object of digestion is to break up the large molecules of beefsteak and bread into the small ones of peptone and maltose, so that they may readily pass through the atomic sieves, which are known as mucous membranes. Whilst within the liver the process is reversed, and the small molecules of peptone and maltose, which have been absorbed, are reconverted into the larger molecules of albumen, which are fit food for living tissues. Again, it is revealed that whilst most people are fully aware of the dangers of sewer-gas, comparatively few recognize the perils in which they daily live from the poisonous substances formed in their own intestines as the result of imperfect digestion. As is shown by a case reported by Senator in 1868, even enough sulphuretted hydrogen may be generated in a man's own abdomen to cause a fatal relapse. The researches of Ludwig, Schmidt-Mühlheim, Bocci and Brieger, and others are discussed by Dr. Brunton, as showing that alkaloids and other poisonous principles formed in the alimentary canal are capable of producing profound nervous depression or other serious poisoning, a fact which our readers will remember was abundantly confirmed in the Memoir published in this journal some months since, concerning the effect of pepsin peptones injected into the blood.

NERVOUS DISEASES AND THEIR DIAGNOSIS. A TREATISE UPON THE PHENOMENA PRODUCED BY DISEASES OF THE NERVOUS SYSTEM, WITH ESPECIAL REFERENCE TO THE RECOGNITION OF THEIR CAUSES. By H. C. Wood, M.D., LL.D.

Philadelphia: J. B. Lippincott Company, 1887.

In his "Introduction" the author states, "... In the course of years I have gradually adopted a method of instructing students which has seemed to me more in accord with the every-day needs of the medical practitioner, and more apt to lead to a practical understanding of disease of the nervous system than is that adopted in the ordinary treatises upon the subject. When a case offers itself for examination the physician must needs travel from the symptoms back to the lesion, and not from the lesion to the symptoms. He does not say, This man has a clot in the brain, therefore he has hemiplegia; but he begins with the paralysis, and passes from it by the process of induction to the lesion. Hitherto the authors of textbooks have travelled from the lesion to the symptoms. The present treatise is an attempt to follow the route which the practitioner must

pass over daily." In this statement rests not only a more than sufficient reason for placing another book before the profession, but also the general plan of the work, a new departure in medical literature which will find admirers wherever the book is read, and should claim numerous disciples among those who would enlighten the profession in medical matters, especially those connected with a specialty. Too frequently the writings of the specialist mystify rather than elucidate, and serve to impress the medical public with the complexity of such maladies, which only the special skill of the writer, or one of his ilk, can hope to unravel. Not so with the work before us. The exigencies of clinical teaching through a course of years have developed an appreciation of the needs of the student, together with an unusual aptitude for clear and impressive statement.

Chapter i., of seventy-three pages, is devoted to "Paralyses." The various forms of palsies are carefully classified, concisely defined, and, wherever possible, succinctly differentiated. All palsies are divided into *functional* and *organic*, and the latter further divided into six classes, including general palsy, hemiplegia, paraplegia, monoplegia, multiple palsies, and local palsy. Interesting cases of unique or strikingly typical character are interspersed here and elsewhere throughout the work.

Chapter ii., on "Motor Excitements," represents eighty-three pages. Disturbances of motility are divided, for convenience of clinical study, into convulsions, spasms, choreic movements, tremors, automatic movements, and contractions. These symptoms are defined, and the various diseases, of which one or other of them furnish characteristic symptoms, are considered and differentiated. Convulsions are divided into hysteroidal, epileptiform, and tetanic. Epileptiform convulsions are ascribed to idiopathic epilepsy, peripheral irritations, cardiac failure, organic disease of the brain, toxæmia, uræmia, and hysteria. Tetanic convulsions to hysteria, tetanus, poisoning, tetany. The other divisions of the subject are given due attention. The sections on epilepsy, tetanus, and chorea are exceptionally fresh and satisfactory.

Chapter iii., "Reflexes," covers thirteen pages, in which the various expressions of this interesting phenomenon are portrayed.

Chapter iv. deals with the "Disturbances of Equilibration," including disturbances of co-ordination, cerebellar titubation, and vertigo.

In chapter v. "Trophic Lesions" are dealt with in a masterly manner, inducing many who read it to look deeper than the surface for many superficial destructive lesions.

"Sensory Paralysis" in chapter vi., "Sensory Exaltations" in chapter vii., and "Disturbances of Special Senses" in chapter viii., will prove of great interest to the general practitioner, meeting, as he does, so constantly symptoms referable to these classes, which are with difficulty traced to their true source, or given their proper interpretation, until too late to materially benefit the sufferer.

The next two chapters deal with "Disorders of Memory and Consciousness." In the last chapter "Disorders of Intellection" are classified and concisely described. Here, as throughout the work, the characteristics of the author are prominent. Order is brought out of chaos, the mazy fog which gathers about nervous diseases is dispersed; simplicity supplants complexity. Whatever may be the verdict of the specialist, whose mental vision has become adjusted to the aforesaid fog, certainly the general practitioner and the medical student will acknowledge their deep indebtedness to the author for his simplicity, conciseness, absence of ambiguity, and, above all, for the unique idea of tracing a symptom to its source, and enabling all who meet with such stumbling-blocks to properly interpret their significance. Throughout the work gives evidence of the profound student, the alert clinician, and the impressive, thoughtful teacher. The first might have dived to even greater depths than the book makes claim, the second might reach as accurate conclusions in his own inner consciousness, but only the latter, through years of careful effort, could have elucidated the subject so satisfactorily. The interest of the book never flags nor tires; its statements are fresh and crisp.

J. B. WALKER.

THE CURABILITY OF INSANITY: A SERIES OF STUDIES.

By Pliny Earle, A.M., M.D.

Philadelphia: J. B. Lippincott Company, 1887.

This book is composed of eight studies on the subject of the Curability of Insanity, the first of which was written in 1876, the last in 1885. The cause of the writing of the first essay, and therefore of the whole book, was evidently the apparent inferiority in the results obtained by Dr. Earle in the institutions under his care to those achieved in certain other asylums. The essay written in 1876 clearly established the fact that the statistics

given by the various asylums of America were worse than useless, and were so misleading and unfair as that they might well be stigmatized as falsifications. One great source of fallacy was that cases of insanity would be reported over and over again as cured, the cures being merely the development of successive remissions. Thus, in the Friends' Asylum at Frankford, eighty-seven *persons* contributed two hundred and seventy-four recoveries to the statistics of the institution, whilst a close analysis shows that not more than two actual permanent recoveries occurred. A champion cure-maker was afforded in a patient in the Pennsylvania Hospital for the Insane, who was successful in furnishing in his own person thirty-two cures! An analysis of the reports of the State Hospital at Worcester, Mass., showed that seven persons furnished ninety-two recoveries, and "yet two of these persons finally died insane in the hospital, and the third is now an inmate of it, considered hopelessly insane." Of the ninety-two reported recoveries only four were permanent.

Both space and inclination are wanting to follow further the analysis of various asylum reports made by Dr. Earle. The statistics of the asylums were rendered still more favorable not only by confounding persons and cases, but also by a juggling which is little less than criminal. If ten cases originated in a year and seven recovered, these seven were reported as cures of recent cases, while the other three were put into the list of cases sick for more than a year,—*i.e.*, of cases not recent. In this way it was apparently proven in some asylum reports that from ninety to one hundred per cent. of recent cases got well, and justification was obtained for the assertions of Dr. William H. Stokes, of the Mount Hope Institution at Baltimore, Md., that "not merely *nine* out of ten cases of insanity, of a less duration than one year, may be cured, but that *ninety-nine* in a hundred can be radically restored, unless there exists in the individual a strong constitutional tendency to mental disease, or unless circumstances beyond our control, and the injurious tendency of which has been fully explained, intervene to interrupt and disturb the process of cure."

The eighth study of Dr. Earle, written in 1885, is interesting as giving the latest and most reliable data which we have in regard to the curability of insanity. The most reliable previous collocation of cases was that made by Dr. T. A. Chapman, of the Hereford Asylum

of England, in which, out of ninety-three thousand four hundred and forty-three cases of insanity occurring between 1872 and 1882, the percentage of the whole number of recoveries is thirty-eight, or, if recent cases are alone considered, forty-two and one-half. The statistics of twenty-three British asylums, collocated by Dr. Earle himself, give the proportionate recoveries in all cases forty-four per cent., in recent cases fifty-five per cent. In thirty American hospitals whose statistics have been examined and collocated by Dr. Earle himself, the proportion of recoveries, as compared with admissions, is twenty-nine per cent. ; of recent cases, fifty-four per cent.

We cannot further follow the statistics discussed by Dr. Earle. As far as they go they seem to us that the recoveries in the British asylums exceed those in the American institutions by between eight and nine per cent. An important conclusion reached by Dr. Earle is that the per cent. of the reported recoveries in all cases received at the hospitals in this country still continues to diminish. Various causes may be assigned for this, but, to our thinking, *the one* real cause is the increased honesty and care in the making of the statistics. In bringing this about the writings of Dr. Earle have played a very important part, and we are glad that permanent form has been given to work which otherwise might have been buried in the mountains of chaff which largely make up the ever-increasing mountain ranges of American medical periodical literature.

THE PRINCIPLES OF PHARMACOGNOSY. By Friedrich A. Fluckiger, Ph.D., M.D., Professor in the University of Strasburg, and Alexander Tschirch, Ph.D. Translated by Frederick B. Power, Ph.D. New York: Wm. Wood & Co., 1887.

According to the authors of the work before us, the use and primary object of pharmacognosy is the study of botany, zoology, and pharmacy of medicinal agents, and the arrangement of the material in a scientific form by an appropriate and comprehensive representation, so as to subject it to a closer examination. The term pharmacology they restrict to the science which treats of the therapeutic action of medicinal agents. In most of our English works pharmacology is considered as comprehending the study of everything that relates to medicines. In treating pharmacognosy the authors consider the following points as prominent: first, naming the plant; second, the geographical distribution; third, cultivation; fourth, col-

lection and appropriation; fifth, commercial relations; sixth, description; seventh, morphological characters; eighth, microscopic structure; ninth, chemical constituents; tenth, substitution and adulterations; eleventh, history; twelfth, pharmacognostical systems. The great bulk of the work, namely, from page 55 to page 279, is chiefly a study of the anatomy of plants. It is very fully illustrated with nearly two hundred figures, which are well drawn and characteristic, and of great value to those students of pharmacy who desire to precede their study of the individual drugs by a thorough education in the anatomy of plants, and especially of those portions of the plants which contain medicinal agents.

To the physician this book does not appeal very strongly. The professions of pharmacy and medicine are more and more divorced as progress increases in each branch the extent of the field to be covered by its students. The modern and growing method of preparing medicinal agents on an immense scale, and furnishing them to the practitioner and to the druggist all ready for exhibition, bids fair to choke out even the scientific pharmacist, and to make the druggist merely a commercial distributing channel, through which pour the rills from the great lake. If this continues, the modern pharmacist must become more and more commercial in his tone and life, whilst a few highly-cultivated scientific specialists find employment in the great manufacturing houses.

Correspondence.

LONDON.

(From our Special Correspondent.)

Since my last letter to you an event has occurred in our pharmacological world which gives us the liveliest satisfaction, and which I am sure will awaken similar sentiments in yourselves when its significance is fully appreciated. I refer to the appointment of Dr. Cash to the important chair of *Materia Medica* in the University of Aberdeen. Your readers have doubtless heard of the distressing death of Dr. Davidson, the late professor,—how he fell down apoplectic in the presence of his students, a victim of constitutional gout, against which he had struggled manfully and patiently for many years. To worthily fill the post left vacant by such a man was no easy task. But beyond the question of mere

ability, it was felt by those who have the advancement of scientific pharmacology in this country at heart, that the present opportunity was not to be lost of planting a centre in the far north which should extend a knowledge of the newer methods and the more exact results of therapeutical research to the farthest extremity of the kingdom. Dr. Cash is known throughout the world of medicine by the many valuable contributions which he has made to physiology and pharmacology, in connection especially with his old master Ludwig, and more recently with his friend Dr. Lauder Brunton, whom he has assisted for several years. His candidature was therefore warmly supported by many of our leading men; yet for a time the issue was doubtful, a disturbing rumor being raised that a distinguished Aberdeen surgeon was to succeed to the vacant chair by a kind of local right. Nothing could possibly be more undesirable than that the work of a great department such as this should be allowed to degenerate into a series of dry lectures on the *materia medica*, with a compilation of the latest therapeutical applications of drugs arranged on a purely empirical basis. This is the kind of course which was generally accepted in our country until within the last few years. The government, which in the present instance possessed the patronage of the chair, is to be congratulated on its choice, and the northern university on the latest addition to their professorial staff.

It occurs to me, in connection with this event, that your readers may be pleased to learn something about our ancient Scottish universities. I say "learn," for I cannot expect that the profession in the States can possibly be generally conversant with institutions which are but imperfectly known and understood even in England. Whilst in London we have now no fewer than twelve schools of medicine, all perfectly self-supporting and independent of the state, and whilst our only university was founded but fifty years ago, and is nothing more than a complicated examining machine without professors or pupils, Scotland possesses four universities subsidized by the nation, of venerable age, the centres of the greatest literary and scientific activity. Edinburgh and Glasgow, St. Andrew's and Aberdeen, are universities in the proper sense of the word,—universities founded originally on Italian and French models, but now approximating more closely in many respects to the German type, with which many of your readers are personally familiar. The professors are chosen from the most distinguished

men of the three kingdoms. They enjoy an income, from salary and fees, which is always ample, and in many instances very handsome,—at Edinburgh, for example, several of the medical chairs are worth over two thousand pounds a year. The general control of the universities is vested in a small court, on which are representatives of the graduates, the crown, and the students respectively. The graduates hold a council or convocation on fixed and special occasions, and publicly discuss the affairs of their alma mater. The executive body is practically the senate, which is composed of the professors and principal, and which exercises full control over the students not only in college but out of college. I need hardly add that the many advantages of university life are fully enjoyed by Scotch students, who display all the traditional independence, the sense of self-importance, and the antagonism to “the town,” which appear to be essential features of the undergraduate in every country. In surroundings such as these, and with an assured competence, Scottish professors are free to devote their whole time and energies to their special work,—to the discovery, that is, and the exposition of the truth. Those members of the medical faculty who desire hospital and consulting practice may usually secure it by their talents and general claims, and can carry it on without that harassing waste of time and energy, that incessant worry, of which I hear so much complaint from our busier men in London. These remarks apply particularly to the University of Aberdeen, where you may confidently look for much good work from the new pharmacological department. The place is filled with traditions of honest labor and learning. Founded in 1494, in the reign of James IV. of Scotland (strange to think, at the very time of the voyages of Columbus!), the University of Aberdeen has produced such men as the Gregorys, Beattie the poet, Reid the philosopher, many mathematicians and physicists of the first rank, and some of the foremost men of science of the present day.

Another very satisfactory sign of the spread of the newer therapeutics is the character of the books that have recently been placed in our hands and in the hands of students by recognized authorities on this subject. Prominent among these is the great work by Dr. Lauder Brunton, which, I am glad to see, has already reached a third edition. This book is as well known with you as it is with us, having been adapted to your Pharmacopœia by Dr. Williams. Your readers will learn with some

amusement that Dr. Brunton has been charged with borrowing from the homœopaths in the compilation of his therapeutical index. Ingenious and persistent efforts have been made to drag him into a public controversy on this subject in the columns of the medical journals,—into a controversy, of course, of that endless, useless kind of which we have all been heartily sick as often as the different therapeutic schools have assailed one another. In the present instance the gauntlet has been thrown down by a highly respectable homœopathic practitioner in town of the name of Dr. Dudgeon, who enjoyed no doubt the opportunity which his challenge afforded him, of standing forth as the champion of truth and reason. With characteristic Scottish caution, and with the tacit approval of all who have had experience in such matters, Dr. Brunton has denied himself the pleasure of public combat. However, on being again assailed in the *Lancet*, he has replied that he will join issue with his opponent,—not in the pages of the medical press, but in the preface to the new edition of his book. We do not expect to find the promised discussion the most profitable portion of the new volume, for, as I have just said, controversies of this kind are usually utterly barren of good results; but for all that we shall turn to it with interest, not to say amusement, as a little incident in the history of therapeutics.

A very important question has lately arisen in this country in connection with our Pharmacopœia, namely, whether the preparations contained in it are strictly official. A public analyst in Sheffield discovered that some samples of tincture of opium that he had caused to be purchased in the town contained a very insufficient amount both of opium and of spirit. When the case was brought before the magistrate it was dismissed, the worthy justice being of opinion that “tincture of opium” means *any* tincture of opium; that the chemist may dispense any compound of opium and spirit he pleases under this name; that there is no law to compel a pharmacist to follow the British Pharmacopœia formula. This is a startling finding for us, who have always believed that “official” remedies are the only compounds that may be sold *under the official titles*; and I need hardly say that it has caused a flutter not only among the pharmacists but in the profession. If there be no better definition of tincture of opium, as sold in this country, than *any* tincture made from opium, there is an end of prescribing. However, we have good reason to believe that the Sheffield

magistrate gave judgment on insufficient information. It appears that although the Medical Act which directs that the first British Pharmacopœia should be compiled did not explicitly command it to be followed, it distinctly confirmed all previous Acts and Orders in Council relating to the London, Edinburgh, and Dublin Pharmacopœias, and that one of these orders expressly charges "all apothecaries and others whose business it is to compound medicines . . . within Her Majesty's kingdom . . . that they do not compound or make any medicine or medicinal receipt or prescription, or distil any oil or waters, or make other extracts that are or shall be in the Pharmacopœia, . . . in any other manner or form than is or shall be directed, prescribed, and set down by the said book."

The discussion of this subject has naturally raised the question of the meaning and value of a "national" Pharmacopœia. We understand that in the States your Pharmacopœia is not the production and property of the nation; that it is only a convenient compilation of formulæ for preparing drugs which your pharmacists may or may not follow. I may be wrong in this interpretation; but if I am right, do you not run a constant risk of obtaining improper substitutes for officinal preparations at the hands of unscrupulous druggists?

Another question in connection with our British Pharmacopœia which has recently been exercising us, is the best method of keeping it up to date. So rapid is the advance of pharmacology nowadays that the Pharmacopœia speedily becomes obsolete. The last British Pharmacopœia (1867) was almost useless for this reason before the appearance of its successor in 1885, and even this "new" Pharmacopœia, as we still call it, already begins to fall behind the times in a similar fashion. Our Pharmacopœia is published by the General Medical Council, a body composed of representatives of all the licensing medical authorities in the three kingdoms (including, of course, the universities), of the practitioners of medicine and of the crown. This council has entire control of medical education and legislation in this country, and one of its committees compiles our national codex. I have been favored with a copy of the report of this committee, presented to the council at its winter session a few days ago; and I find in it a valuable recommendation as to the plan to be adopted for keeping the Pharmacopœia up to date. This scheme has been framed by Professor

Attfeld, whose fame as a chemist is as great with you as with ourselves, and whose services have most wisely been retained as reporter by the council after the completion of the present British Pharmacopœia, the production of which was in a great measure his work. Dr. Attfeld submits to the council a collection of abstracts of all published criticisms of the British Pharmacopœia and technical suggestions, as well as notes of all original investigations, that seemed likely in any way to aid in the production of a future Pharmacopœia. He recommends that these and similar abstracts and notes in the future be printed (for official use only) and submitted to the standing committee, which will thus steadily acquire the materials for the production of a new codex, or for the correction of the present codex, as circumstances may demand. Already, Dr. Attfeld adds, since the current Pharmacopœia was issued, there have been published some valuable improvements of official processes,—improvements which may deserve incorporation. Prominent among these improvements are methods for securing constant strength in powerful remedies, hitherto liable to vary considerably in strength. The processes that provide for fairly constant strength in the preparations of cinchona, nux vomica, and opium appear likely to be extended to preparations of belladonna, ipecacuanha, and some other potent drugs. A dispensing difficulty, however, has arisen in connection with the semi-solid "standardized" extracts of such drugs. Inasmuch as the non-alkaloidal soluble material in nux vomica seeds, *e.g.*, varies greatly in different parcels, it follows that an extract evaporated to the proper alkaloidal strength, while occasionally of fit pilular consistence, will sometimes be almost fluid. Such a difficulty can be surmounted by adding some solid neutral substance, such as milk sugar, to the soft extract to bring it to the desired pilular firmness. British pharmacists, however, bearing in mind the action of the Food and Drug Acts, hesitate to add foreign substances to their drugs without official sanction. Custom, however, sanctions the employment of excipients by the pharmacist at his discretion, and he doubtless will sooner or later find modes of adjusting the advantage of constancy in strength of powerful drugs with inconvenience in dispensing such "standardized" drugs. I may remark with respect to the variable consistence of standardized extracts, referred to by Dr. Attfeld, that custom is changing here in the manner of *pre-*

scribing pills. Few of us now seriously attempt to express our familiarity with the consistence of an extract. We very commonly order the quantities which we desire of the important ingredients, and complete the prescription with "*in formâ pilulâ*," leaving the intelligent pharmacist (and all our pharmacists are now required by law to be intelligent in such matters) to find the most suitable excipient for himself.

BERLIN.

(From our Special Correspondent.)

The medical world of Germany is suffering from a loss, which is almost irreparable, in the death of Carl Schröder, who died on February 7, after a brief illness, of cerebral abscess. He was the most celebrated German gynecologist of the present time. Schröder had attained world-wide reputation through his two books, which marked epochs in medicine, his "Text-Book on Obstetrics, including the Pathology of Pregnancy and the Puerperal State," and his "Handbook of Diseases of the Sexual Organs of Women." He was only thirty-eight years old when, in 1876, he was chosen to succeed E. Martin as regular professor of the Lying-in and Gynecological Clinic, and went to Berlin. One of his most remarkable achievements was the erection and remodelling of the clinic building, which is regarded as the best of its kind by the physicians and students of the nation.

Schröder was only permitted to enjoy a little more than four years' usefulness in this institution when he died at the age of forty-nine, in the height of his scientific activity. His latest work, published last year, "The Pregnant and Parturient Uterus," proves how much we could have expected from him.

Foreigners, especially Americans, many of whom are numbered among his students, will join us in regretting his loss.

From the 13th to the 16th of April will be held the sixteenth congress of the German Surgical Association, under the presidency of R. von Volkmann, and about the same time the Sixth Congress for Internal Medicine will be held in Wiesbaden, with Leyden as president: the latter congress has already announced its programme. One day's consideration will be given to the "Therapy of Phthisis," the "Localization of Cerebral Diseases," and the "Pathology and Therapy of Pertussis."

The first subject will be of especial interest,

as giving the views of this great association, which numbers among its members many of the greatest living authorities with regard to the many recently recommended methods of treatment in phthisis; and the physicians discussing the question will endeavor to bring the therapy of this disease into accord with their own experience and best knowledge.

We shall report this congress for the readers of the GAZETTE.

A new periodical has recently appeared in Berlin, under the editorship of Professor Liebreich, called the *Therapeutic Monthly*. Its purpose and scope are similar to that of the THERAPEUTIC GAZETTE in America, the *Practitioner* in England, and the *Bulletin de Thérapeutique* of France, and to form a repository for matters of interest regarding therapeutic questions. Up to the present time there has been no such organ, although there is an abundance of valuable journals in Berlin.

We mentioned in our former letter the results obtained by Harrlich in Leyden's clinic in the treatment of joint-rheumatism. At a later meeting of the Society for Internal Medicine the same observer continued his remarks, and discussed the effects of salol in the treatment of acute infectious diseases, especially typhoid fever. He came to the conclusion that, although the remedy proposed accomplished as much as was claimed for the carbolic acid treatment of typhoid, it had developed no specific power in infectious diseases, and especially in typhoid. It cannot shorten the disease nor cut short the process of infection, as quinine acts in malaria. The satisfactory use of salol in typhoid is limited to its effect upon the symptoms only; as an antiseptic, in common with others, it may be valuable to reduce temperature. In a number of severe cases, which have been under observation for some time, when pure salicylic acid had been given, salol was not found to be excreted; the possibility of the combination of salicylic with carbolic acid in the organism is to be considered.

Guttmann, of the "Moabit" hospital, has reached the same conclusions after treating seventeen cases of acute joint-rheumatism and several cases of typhoid.

Fränkel has given us a new indication for the use of massage in a lecture delivered before the Society for Internal Medicine upon weakness in vocalization. The six cases on which he based his theory were four singers, a clergyman, and a teacher. All of the cases showed marked inability to use the voice at

certain times when attempting to sing, to accent in a loud voice, and to emphasize a pathetic passage in an address. This aphonia, however, could be overcome by a strong volition. Laryngoscopic examination gave a negative result. Simulation and hysterical paralysis were excluded. Following the analogy of the name *mogigraphia* for writer's cramp, Fränkel has named this affection *mogiphonia*. In the last case described by this writer the following treatment was pursued: the throat of the singer was well rubbed with lanolin, and both sides simultaneously, beginning at the angle of the jaw and extending downward. At the anterior border of the sterno-cleido-mastoid muscles the fingers on each side pressed the larynx as closely as possible without pain. This massage was repeated daily at sittings at which fifty frictions over the larynx were made, and the hand was also carried across the throat at the *os hyoides*. After a very few days a marked improvement was noticed, and in six weeks the patient was able to sing for more than half an hour. Fränkel urges the adoption of his method in similar cases.

Langenbeck, director of the Lazarus Hospital, reports in the Berlin Medical Association the following interesting experiences in cholecystotomy and cholecystectomy. In cases which have resisted internal treatment, and where surgical treatment seems indicated, he prefers extirpation of the gall-bladder to all other procedures. He has already operated upon twelve cases, of whom only two have died from complications; the others recovered, and of these it is known that several have enjoyed good health for four or five years. In chronic obstruction of the gall-duct Langenbeck operated three times; in one case he failed to render the duct patulous; in two others he evacuated the abscess, which had formed at the obstruction, removing pus mixed with bile; one of these cases he showed to the society. In this case an exploratory incision found the gall-bladder very much contracted, and cholecystotomy was determined upon. On opening the gall-bladder there was a discharge of thick greenish-gray pus. The patient recovered rapidly. In two or three weeks the discharge from the gall-bladder ceased; bile was present in considerable amount in the intestines, the feces were dark brown in color, and the stools occurred regularly.

After six or seven weeks the fistula which had been formed closed entirely. In the other similar cases the fistulae have not en-

tirely closed, a very fine opening remaining, from which a little bile is at times discharged. In the same society, on February 9, Professor Küster, director of the Surgical Department of the Augusta Hospital, demonstrated one of the very rare cases of originally diagnosed pancreatic cysts.

Up to the present time there have been but eleven cases of cysts of the pancreas operated upon, and of these nine were incorrectly diagnosed. The correct diagnoses were those of Gussenbauer, of Prague, and Senn, of Chicago, and these diagnoses were those of a high degree of probability only.

The case demonstrated was that of a strong man, 46 years old, who had suffered very little ill health, but who had eight years previous sustained a severe contusion of the back from a fall. In the summer of 1885 he was frequently attacked by cardialgia, which, in December of that year, became so severe that he sought medical treatment. About the end of February, 1886, a tumor in the epigastrium was discovered. On the 15th of July, 1886, he came to Prof. Küster for treatment with the diagnosis of *echinococcus* of the liver. On careful examination it was seen that the tumor fluctuated and showed distinct pulsation. Percussion proved that it was not attached to the liver. Exploratory puncture revealed a dirty yellow-colored liquid containing much albumen. Examination with the microscope showed a large number of red blood-corpuscles. All of these signs led Küster to diagnose a pancreatic cyst. He reached this conclusion from the position of the tumor, and by excluding the following conditions: aneurism of the abdominal aorta and its branches; cysts of the suprarenal capsules; *echinococcus* of the liver and spleen; enlarged lymphatics; ovarian cysts were excluded by the patient's sex; malignant, small tumors in this region; after careful study of these conditions, it was thought to be correctly diagnosed as a pancreatic cyst, and an operation deemed advisable. On July 20 the abdomen was opened by an incision which extended from the tip of the sternum to a point one and one-quarter inches below the umbilicus. A large cyst at once presented, its upper extremity covered by the stomach, its lower extremity by the transverse colon. The ligamentum gastro-colicum was adherent to the cyst; the latter was partially detached and cut across, and its flaps sewed to the abdominal wall. The cyst proper, thus separated from its adhesion, was punctured and emptied of two and one-half quarts of liquid.

It was then incised transversely, and sewed for a second time to the wall of the abdomen ; its cavity was cleansed and tamponed with iodoform gauze, and the incision almost closed.

On August 18 the wound was entirely closed, except a very small fistula, which was also healed by September 2. The patient had suffered no inconvenience, and had gained forty pounds in weight. Up to the present time there are three methods of operating for cysts of the pancreas,—simple puncture and evacuation, extirpation, and incision and sewing the sac to the abdominal wall. Kuster decides without question in favor of the third method. Of the five cases of extirpation four died ; in contrast is the result of the six cases where incision and suturing were done. All recovered, and five made speedy recoveries to comfortable health ; in only one a small fistula persisted.

February 21, 1887.

PARIS.

(From our Special Correspondent.)

The study of alkaloids and active principles is always of some importance, as they most likely represent the *materia medica* of the future. For this reason all recent experiments, chemical or physiological, respecting the older or the comparatively new alkaloids, or active principles, are generally deserving of notice.

The latest to receive the attention of French investigators are digitaline, hyoscine, and ulexine. *Digitaline* is certainly not a new-comer. The trouble is there are several substances known as digitaline, some of German make, others of French manufacture, and none seem to be exactly alike. In fact, there are too many digitalines. M. Lafon, in a paper which was this year awarded the Baignet prize by the Academy of Medicine, has again attempted the solution of a difficult and much vexed question, which he had already investigated. Although it cannot be said he has entirely succeeded, the results arrived at are worth recording. Briefly stated they are as follows : To begin with the chemical properties, M. Lafon has found a new color reaction of digitaline. When the substance in question is moistened with a small quantity of sulphuric acid, mixed with an equal weight of alcohol, on gently heating, and adding a trace of dilute perchloride of iron, a magnificent greenish-blue coloration

is obtained, which persists for twenty-four hours.

Physically and chemically (1) all the French crystallized digitalines are nearly identical ; (2) Homolle and Quévenne's digitaline and the Codex amorphous digitaline are very nearly identical with the German *digitoxine* ; (3) German digitalines are quite different from the French. Toxically (1) the crystallized digitalines—either Nativelle's, Homolle and Quévenne's, or Duquesnel's—are substantially alike, from 2 to 3 centigrammes being sufficient to kill a dog weighing twelve to fifteen kilogrammes ; (2) the amorphous French digitalines—Codex chloroformic, Homolle and Quévenne's, etc.—have very sensibly the same toxic power ; (3) the product sold in Germany under the name of *digitoxine*, and considered there the most active principle in *digitalis*, possesses about the same toxicity as crystallized digitalines.

Physiologically digitaline acts as follows : (1) Its absorption is very slow. (2) It is not eliminated by the kidneys ; its presence never being detected in urine. (3) It appears to accumulate in no particular organ, at least in the shape of digitaline. All chemical tests failed to detect it in one organ more than in another, after acute or after slow poisoning. (4) It is not sensibly modified in the digestive tube, but possibly may be oxidized in the circulatory organs. (5) Digitaline is with difficulty altered by chemical and physical agents, fermentation, and putrefaction. Two things at least seem clear from M. Lafon's investigations, namely, that German *digitoxine* and French digitaline are substantially identical, and that German digitaline is a product quite different from either.

The physiological action of *hyoscine*—an alkaloid derived from *hyoscyamine*—was examined and discussed at a meeting of the Paris Société de Biologie (March 19). Messrs. Gley and Rondeau related that hydrochlorate of hyoscine, in the dose of 1 centigramme for a medium-sized dog, has a soporific influence. In larger doses the moderating effect of the pneumogastric nerve on the heart is suppressed, and the same happened in respect to the action of the chorda tympani on the secretion of the submaxillary gland. Clinical experiments with about fifty patients have shown very speedy and powerful mydriatic effects to be obtainable from one drop of a one per cent. solution of hyoscine hydrochlorate. On being questioned by M. Laborde, M. Gley added that hyoscine and atropine greatly differ as regards their my-

driatic action. With hyoscine the maximum dilatation of the pupil is observed after six, or, at most, eight minutes, while with atropine from twelve to twenty minutes are necessary. Besides, physiologically, hyoscine possesses hypnotic properties not found in atropine, except perhaps in very high doses. Another difference, M. Laborde thought, is that the effects of hyoscine are more persistent.

Physiological Properties of Ulexine.—Ulexine is an alkaloid found by A. W. Gerrard in the seeds of the *Ulex Europæus*, common furze or gorse, a thorny plant growing wild in the temperate regions of Europe. In fact, English and French farmers rather consider the bush a nuisance, only fit for the fireplace; while, if Sowerby be believed, Linnæus, on his first visit to England, at the sight of the flowering shrub in Hounslow Heath, fell on his knees, and thanked God for having created a plant so beautiful. The same diversity of opinion appears to prevail in regard to the properties of the alkaloid. The process for preparing ulexine, briefly stated, consists in exhausting with alcohol of eighty-four degrees the coarsely-powdered seeds, evaporating the percolate to syrupy consistence, and washing this extract with successive portions of water. The watery solution, which now contains the alkaloid, is concentrated by evaporation, and shaken with chloroform in the presence of an excess of ammonia. The impure chloroformic solution of the alkaloid being purified by several solutions in acid water and re-precipitations, too well known to here need description, the substance is finally obtained in the shape of crystalline masses, which are colorless, inodorous, and soluble in water. The alkaloid has a bitter, slightly acrid taste. It forms definite and crystallizable salts, of which the hydrochlorate, being very soluble in water, was selected for a series of experiments performed by Dr. Pinet, in Prof. Vulpian's laboratory, under the professor's advice and supervision. The results of the investigation, just published in *Arch. de Physiol.*, No. 2, are the following: To begin with, Dr. Pinet differs from the English opinion that "ulexine is a paralyzer, able to cause clonic convulsions; on the tongue the effect is somewhat like that of cocaine, but less marked."* Ulexine convulsions have been found to much resemble those caused by nicotine. They begin within three minutes after hypodermic administration; after from five to seven minutes the animal is semi-

comatose, respiratory motions cease, but the cardiac beatings persist. Ulexine appears to affect, not the muscular, but the nervous system, beginning with the central and ending with the peripheric nervous system.

For a frog weighing thirty grammes (one ounce) 5 milligrammes ($\frac{1}{12}$ of a grain) of ulexine is a lethal dose. The heart-beats become weaker and weaker, and stop in the diastole. A non-mortal dose—1 milligramme—for an animal of the same size brings on convulsions and narcosis; the heart keeps beating, muscular contractility remains intact in all cases, and the local anæsthesia mentioned by English writers, and compared by them to that of cocaine, has never been observed by Dr. Pinet.

With a guinea-pig weighing three hundred and twenty grammes (ten and one-half ounces) 5 milligrammes of ulexine have no effect. It takes 1 centigramme ($\frac{1}{10}$ of a grain) to affect the animal. Somnolence, heaviness, and slight narcosis ensue, and the creature dies asleep, as it were.

Ulexine not an Antidote against Strychnine.—The narcotic properties of ulexine naturally led Dr. Pinet to try whether it is physiologically antagonistic to strychnine. To a limited extent it is, and even but temporarily so. The effects of ulexine are very speedy, so that when administered after strychnine it masks for a while the tetanic action of the first alkaloid, and apparent immunity results. But soon the influence of ulexine vanishes, and strychnine, gradually resuming the mastery, again exerts its usual effects.

And now to turn from the study of therapeutic agents for their own sake to the medicaments recommended for special affections, several novel modes of treatment have been spoken of by French practitioners. Among them may be noticed two remedies for diabetes, and a very simple one for deficient lactation.

Belladonna and Opium in Acute Diabetes.—In a memoir read before the Academy of Sciences at one of its sittings in February (14), Dr. Villemin related a case, unfortunately alone of its kind, but very interesting in itself. It was as follows: On March 11, 1882, a young artilleryman was sent for treatment to the Val-de-Grâce military hospital in Paris. The patient, a tall, stout-limbed young man, complained of failing strength, cramps, muscular pains, and sore throat; his thirst nothing could quench, and his hunger nothing could sate. But the aliments afforded no strength, and the liquids only passed off in

* The English text is not quoted by Dr. Pinet.

the urine, which had become so abundant as to interfere with sleep. Upon analysis, glucose was at once detected, in the proportion of fifty-eight grammes per litre, which, at the rate of fourteen litres and a half voided in twenty-four hours, corresponds to eight hundred and forty-one grammes, or nearly two pounds of glucose.

At first the usual treatment was resorted to, namely, gluten bread, meat, alkalies, abstinence from sugar and starchy foods, etc. But after eight days no improvement had occurred; the urine still kept at between twelve and fourteen litres; the proportion of sugar remained nearly the same, and a fatal ending was evidently near, when Dr. Villemin thought of trying on his glucosuric patient the belladonna and opium treatment, which had proved successful with another one suffering from diabetes insipidus.

It was not, however, without some misgivings lest glycemic accidents might be brought on, and therefore great caution was at first observed. On March 20 10 centigrammes ($1\frac{1}{2}$ grains) of extract of belladonna and 5 centigrammes ($\frac{3}{4}$ of a grain) of aqueous extract of opium were administered within twenty-four hours, the same being continued to the 27th. On that day the quantity of urine had fallen down to ten litres, and the sugar to forty grammes per litre. The doses were now gradually increased, so that on May 20 they had become 15 centigrammes ($2\frac{1}{2}$ grains) of each extract. The urine was at that time reduced to between three and four litres a day, with a proportion of sugar varying between two and five grammes per litre. From May 20 the dose was increased to 20 centigrammes (3 grains); eight days later the sugar had disappeared altogether. For seventeen days longer the treatment was continued, without any reappearance of glucose being observed. On June 14, the medicines having been suddenly withheld, the sugar within three days reached again sixteen grammes per day. The medication being then resumed, the sugar disappeared as before, and the patient kept well, under its influence, for over five weeks, when bromide of potassium was near the end of August substituted for the narcotic extracts. The relapse was as remarkable as before, and the same effect resulted when either the opium or the belladonna were omitted from the daily dose. Hence Dr. Villemin insists upon the importance of associating the two substances together. On December 15 the patient, having recovered nearly his usual weight and ap-

parent health, insisted upon leaving the hospital. He was discharged, and never heard of again.

Arsenic and Lithia for Diabetes.—At a meeting of the Paris Société de Thérapeutique (February 23) Dr. Martineau recommended the following treatment, with which, he said, he had cured sixty-seven out of seventy patients suffering from arthritic diabetes:

Carbonate of lithium, 3 grains;
Arsenate of sodium, $\frac{1}{10}$ grain;
Carbonic acid water, 2 pints.

Effect the solution under pressure. The effervescing liquid is to be drunk at meals, mixed with claret, and the foregoing dose is to last for at least three meals, being taken at the two principal meals of the day, customary in Paris. No change of diet is necessary. Dr. Martineau's fellow-members—Dr. Dujardin-Beaumetz among them—were somewhat sceptical about the value of the treatment, but it is so simple and easy that it can be given a trial when the patient is not dangerously ill.

Electricity to promote Lactation.—Dr. H. Pierron, a well-known gynæcologist, calls attention to the use of electricity for exciting the mammary secretion when no apparent reason exists for its failing. Without claiming invention, or even priority, he says he was first induced in 1884, upon theoretical grounds, to try it in the case of a lady patient who was anxious to nurse her own child. Although in excellent health, and everything had been done that science could suggest and wealth afford, she was unable to supply the child with enough nourishment. Dr. Pierron was successful in obtaining the desired result by means of the intermittent current of Gaëffe's induction apparatus applied to the mammary glands. The secretion thus secured was abundant and excellent in quality.

Since then the same treatment has been satisfactorily employed in all similar cases, to the exclusion of other means, when lately a difficulty of another sort occurred. A primipara had weaned her baby, but after fifteen days she noticed it was declining and pining for the breast, scarcely touching other food. In the mean time the lactary secretion had ceased, and menstruation resumed its course. The electric treatment was again resorted to, and after four applications full breasts were the result, with an abundance of good milk, and for the last two months everything has been going on to the satisfaction of all concerned.

The mode of operating with Gaëffe's apparatus is as follows: The negative pole, a spheroidal copper or brass cap, is to be applied under the breast. The positive pole, a round copper ball, is then first placed near the nipple, so as to touch the foldings of the skin, thus stimulating the glandular orifices to begin with. The positive pole is next moved around over the whole mammary gland, working from the centre to the periphery, while the negative pole, which it is approaching, follows its motion at the base of the breast. The same operation is to be performed on each breast in succession at one sitting, but the electric current must at first be weak enough to cause no pain on an organ naturally very sensitive. A second application is made at the same sitting with a current slightly stronger, and the whole together must not last more than ten minutes. The performance is to be repeated every twenty-four hours, and four applications are usually sufficient to cause the flow of milk, when it has only been delayed. When the secretion has already been purposely suppressed, the physician should not despair if he has to renew the operation eight times.

To conclude with a piece of news, Dr. Bergeron was yesterday (March 22) elected perpetual secretary of the Academy of Medicine, in place of the late Dr. Béclard. The contest was very close, as Dr. Jaccoud was also a candidate for the office. At the first ballot Dr. Bergeron obtained forty-six votes out of ninety-one, exactly the necessary majority. Great interest was felt in the election. Even M. Berthelot, the present Minister of Public Instruction, had left the ministerial palace, and sat in his seat, whence he recorded his vote like a simple Academician.

ABORTION FOLLOWING THE USE OF PERMANGANATE OF POTASSIUM.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—I was called February 25 to see Mrs. B., aged about 35. She said at her last menstrual period she had flowed only two days, and since then had not felt her usual self. It was time for to be unwell again. A day before she got wet. She was positive that she was not pregnant. She suffered with intense headache, backache, and soreness, slight elevation of temperature, and vomiting.

I gave her morphine for the headache and aconite, not having any permanganate with me. The next day she was somewhat better, and I then left her eight 2-grain capsules of

permanganate of potassium, one to be taken three times a day. The first one she vomited, the second and others were retained with difficulty and only by drinking freely of water.

The next day she began to flow, and flowed very freely that night. I saw her the next day.

The cervix uteri was well dilated and something protruding, which was thoroughly removed, and found to be a foetus a month old. Recovery good.

Although Merrill and Ringer said the permanganate had no action on a gravid uterus, this is not the first case of abortion following its use.

S. B. SPERRY, M.D.

DELAFIELD, WIS.

URTICARIA FROM INDIGESTION.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—Dr. R. L. Hutton, of Prescott, Ark., has a communication in the THERAPEUTIC GAZETTE for March relative to urticaria due to indigestion, which is answered and commented upon by the editors. My experience in this difficulty coincides with the expressed views of the editors of the THERAPEUTIC GAZETTE, and is unlike that of Dr. Hutton, so far as regards his statement that the disorder is confined to the male sex of middle age. I have found that women, without regard to age, are as liable to be attacked as men. Indeed, I am quite positive I have treated more women than men for this difficulty, nor have I had occasion to notice that it is confined to those individuals of a gouty diathesis, who as stated by the editors of the GAZETTE are most likely to suffer. I have a patient at this present writing, whose sudden, distressing, and unexpected, though, fortunately, infrequent attacks, present some interesting features. The patient is a young married woman, aged 23 years. Generally speaking is a healthy, but not robust, woman. Has no history of gout, and is by no means a chronic dyspeptic. At irregular intervals of from two to six months, about an hour following a usual meal, she will be suddenly and without warning attacked with distressing dyspnoea and marked asthmatic symptoms, so that the first time I was called to her I was misled in believing it to be a genuine case of asthma. Within half an hour there is felt a general benumbed sensation over the entire surface of the body, and within a few minutes the urticaria makes its appearance in large elevated irregular blotches

in different parts of the body, showing itself in successive crops. It arises almost instantaneously, first in one place then in another, over the limbs and trunk. The itching is simply unendurable, and the inclination to scratch irresistible. This patient, though exceedingly modest and ladylike, during this stage of the attack became thoroughly indifferent as to position, posture, or exposure of person in order to scratch any offending portion. Is utterly unable to keep quiet in any position an instant, and in every way shows acute suffering. How long this stage would continue is doubtful, but I have always been able to relieve her distressing condition by a prompt emetic. The contents of the stomach vomited is undigested food in large quantities. As soon as emesis is procured, the symptoms and urticaria disappear almost instantly, and five minutes later the patient is perfectly well, without an unpleasant sensation or a sign of the eruption.

H. D. THOMASON, M.D.

ALBION, MICH.

THE USE OF GALVANISM IN THE TREATMENT OF INDOLENT ULCERS.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—I want to say a few words here about a case that my father, Dr. J. Z. Scott, of this place, has been treating during the past winter. It was a case of indolent ulcer, whose history dated back over fifteen years. At the commencement there was a periostitis, which resulted in destruction of tissue, and finally ulceration, and sequestra of bone were thrown out at different times, until finally it seems all the dead bone was thrown off; at least no dead bone or signs of such could be discovered by the usual exploratory methods.

But the general health of the young man, who was about 20 years old, was impaired, and a condition of the body obtained that seemed to encourage a kind of chronic ulceration process. He had been treated by several reputable physicians before he called upon my father, but had not been benefited much.

When my father saw him first, the ulcer, which was situated an inch above the internal malleolus, extending across the leg transversely to the subcutaneous border of the tibia, and internally about two inches, was painful and very tender, but was indolent as to its general characteristics.

The boy could not sleep much at night on

account of the severe pain. He was placed on an emulsion of cod-liver oil, syr. hypophosphites, lime and soda, and pancreatic emulsion, in this formula:

R Cod-liver oil, ℥iv;
Pancreatic emulsion, ℥ss;
Syr. hypophosphites lime and soda, q.s. ℥vi. M.
Ft. emulsion.

Sig.—A tablespoonful two hours after each meal, and a pill of iron, quinine, and arsenic, with co. ex. of colocynth, as follows:

R Acid. arsenic. gr. i;
Ferri subcarb., gr. xxx;
Ex. colocynth. co., gr. xx;
Pulvis piper. nig., gr. xl;
Ex. taraxacum, gr. xxx. M.
Ft. pil. No. 40 in caps.
Sig.—Take one each night.

He used as a local application iodoform ung. and eucalyptus ung., and strapped the parts well with adhesive plaster. He kept up this treatment for several weeks, but never obtained relief until he commenced the use of the galvanic battery. The secretions of the ulcer were noticed to be alkaline, and the negative pole was placed to the ulcer, the positive at some indifferent point, and six cells were taken into the circuit; the séance was prolonged about ten minutes. From that time the ulcer began to get well, and a half-dozen applications ended the case.

He applied the bare silver plate of the negative electrode of the McIntosh galvanic battery directly to the diseased surface. The other treatment was also persevered in. The general health of the young man was improved all the time, but the ulcer never began to undergo healthy changes until the galvanic current was applied to its bare surface.

My father says he is satisfied that it is a useful weapon with which to combat disease of this sort when used intelligently.

FRANK M. SCOTT, M.D.

SCANDIA, KANSAS, March 21, 1887.

Notes and Queries.

THE TREATMENT OF PLACENTA PRÆVIA.

The treatment of placenta prævia is a matter of such importance and obscured by so much diversity of opinion, that we reproduce in full the editorials that appeared on this subject in the *Lancet* for February 25 and March 5, 1887.

Of all the complications of labor, none is more urgent and more serious than hemor-

rhage; and of the causes of hemorrhage none is more important than placenta prævia. The earliest mention of the condition is to be found in the works of Guillemau, in A.D. 1609; and next in those of Mauriceau, A.D. 1668. Their view was that the after-birth was originally situated higher up, but became displaced as pregnancy proceeded, a view which is still extant in the phrase popular among the lower classes and midwives,—“the after-birth slipped.” The correct view, that the after-birth is firmly planted in its dangerous position, was first illustrated by the necropsy of a woman who died of placenta prævia, and was dissected by Schaller in A.D. 1709; and this view was first introduced into the text-books by Johann van Hoorn, A.D. 1715, a pupil of Portal. Van Hoorn plainly says that the cause of the dangerous condition is the after-birth, which at the beginning of pregnancy takes its place on or above the os uteri. After Leveret's time the main facts with regard to placenta prævia are found generally current.

To write a historical review of the subject from that time to this would consume too much of our space; moreover, it would show occasional retrogressions in knowledge and understanding. At the present time our knowledge, which not many years ago was thought to be pretty complete, has been somewhat disturbed by the study of the “lower uterine segment,” to which a great impulse was given by the suggestive studies of Ludwig Bandl on uterine rupture, pursued by him in search of the explanation of many other problems. Bandl's views, which need not here be given at length, were many times modified by their author, but the result of the discussion and observations which they have excited has been to show that during labor the uterine body becomes differentiated into a retracting and ever-thickening fundus, a stretching and ever-thinning “lowest uterine segment,” and the cervix. It is not yet, however, finally settled what is cervix and what is “lower uterine segment.” The lowest part of the retracted fundus is felt after labor as the bottom of the hard uterine cricket-ball; below it come the cervix and “lower uterine segment,” hanging loose, apparently unretracted and passive, like a piece of flabby hose. The question is not yet settled why, if this lower uterine segment is the site of placenta prævia, any woman escapes flooding to death after this complication. Meanwhile it is possible that, though it feels flabby, it may be physiologically retracted to an extent suffi-

cient to control hemorrhage. Having said thus much, we will proceed to be more dogmatic.

And first we would say that the utterances of the text-books on this great subject are most unsatisfactory, being overloaded with detail both as to pathology and treatment, and generally “hedging” each statement with a timidity and uncertainty which appears in the answers of students in examination, and in the treatment of practitioners. It would be worth all the writing which occupies so many pages, and leaves us at the end as uncertain as to the author's views as we were at the beginning, to enunciate a few great propositions, and to get them well absorbed by those whom we have to teach. We will give some of them:

1. The bleeding comes from the placental site.
2. The cause of the bleeding is the detachment of the placenta.
3. The cause of the detachment of the placenta is the expansion of the lower uterine segment, which the placenta is unable to follow.

This will be seen to be equivalent to saying that before labor there is no bleeding. This is generally, but not always, true. We are obliged, therefore, to remark that the beginning of labor is not always synchronous with the beginning of the “first stage” of labor, but begins with the dilatation of the os internum, which may precede the “first stage” by days or even weeks. Also that the bleeding in placenta prævia is often due to the same causes as operate in “accidental hemorrhage,” acting, indeed, with additional advantage on account of the low site of the placenta and the consequently heavier column of blood which the utero-placental vessels have to support under these conditions.

Having plainly stated the main great facts, which are worth all the rest put together, and which should be always taught dogmatically and almost like aphorisms, we now proceed to the question of treatment, for a plain statement of which the student looks in vain in even the most recent text-books, and which seems to us capable of at least an attempt at formulation. We would first remark that a certain number of cases of placenta prævia progress favorably to a safe termination, and require no interference. This is, of course, more likely when only part of the placenta is situated on the area of necessary detachment, but it is not unknown where the placenta is central,—that is, implanted across

the os internum. In such cases the child has been known to be born by strong contractions, wearing the placenta like a cap on its head. On this the well-known treatment of Simpson—the complete detachment of the placenta by the hand,—and its modification by Barnes—partial detachment,—were founded. It is to be remarked that Simpson's treatment was founded on an interpretation of the phenomenon which implied that the woman was delivered safely because the placenta was detached, whereas in our opinion such cases only show that the uterus acted with unusual vigor, shortening the dangerous period and producing good retraction, which, as is well known, is the only safeguard against bleeding. Detachment of the placenta apart from vigorous uterine action is only an increased element of danger. But most cases of placenta prævia do require prompt and wise interference, and to wait for their spontaneous termination would be as wrong as to wait for some form of spontaneous explosion or evolution in a cross-birth. Treatment, to be rational, must be founded on the pathology and natural history of diseases; in other words, it must take cognizance of the causes of death with a view to avoiding them, and of the manner in which nature deals with them when she does so successfully. We come, therefore, to enunciate two more great principles:

4. The great dangers of placenta prævia are: (a) bleeding before and during labor; (b) bleeding after delivery; (c) septic processes.

5. The great safeguard against bleeding before, during, and after delivery is uterine retraction.

We come, therefore, to consider how the dangers arise, how they may be avoided, and how retraction may be secured.

The cause of bleeding before and during delivery has already been touched on. It is detachment of the placenta by dilatation of the placental site. The causes of bleeding after delivery are mainly two,—imperfect retraction, and laceration of the cervix and lower uterine segment, which is, of course, unusually vascular. This also predisposes to sepsis. The causes of sepsis are three,—the low situation of the placental site, bringing it nearer to the outer world and nearer to the accoucheur's fingers, lacerations, and perhaps also imperfect retraction of the lower uterine segment. The great object, therefore, with a view to avoiding and controlling hemorrhage, has been to produce uterine contraction and retraction; and to do this directions have been

given to empty the uterus as soon as possible. The condition of the cervix, which, though soft, is often loath to dilate (probably in connection with the abnormal position of the placenta, which disorders the polarity), has rendered it impossible in many cases to effect this without forced delivery (*accouchement forcé*), which consists in thrusting in the hand and dragging out the foetus by the feet. This is a most dangerous proceeding, and generally takes the practitioner out of the frying-pan of ante-partum hemorrhage into the fire of laceration, post-partum hemorrhage, and blood-poisoning.

Delivery by the head is not suitable for cases of dangerous placenta prævia. No aid can be given till the labor is so far advanced as to be practically over so far as the danger of bleeding is concerned. A sixth proposition may now be enunciated:

6. The great treatment for placenta prævia is turning by the feet.

Our readers will perhaps say, "and extraction." But here we must make another statement, namely, that this is usually unnecessary.

7. It is found practically that as soon as turning has been effected and the leg brought down the bleeding ceases.

The explanation usually given for this is that the presenting part plugs the bleeding site; but it is not certain whether this explanation is correct, or whether the arrest of bleeding is not rather due to the retraction which partial emptying of the uterus effects. It follows, therefore, that—

8. After the leg is brought down, the case may generally be left to nature.

We come now to some points in the history of that condition. Internal version requires dilatation of the cervix to an extent implying that labor has advanced to a considerable degree of progress. To wait for this is often impossible, and *accouchement forcé* (forced delivery) was formerly the only alternative.

The first great advance was made in 1860 by Dr. Braxton Hicks, who showed the possibility of turning by the bipolar method when the cervix would admit two fingers, or even one. He expressly pointed out the advantages of early version by this method in placenta prævia, and published a series of cases to illustrate his point. Our Teutonic brethren seem to have read his publications (which are plain enough) without understanding, for the greatest German accoucheurs, Von Hecker and Spiegelberg, opposed and derided bipolar version, but showed that they failed to comprehend it. In the mean while

various methods of treatment were proposed and partly adopted, and Hicks's method seems to have been practically unknown in France and America. Twenty-two years after its publication a serious trial of early bipolar version was made by Hofmeier, a year later by Behm, and a year later by Lomer, all in Berlin. It was then found that the method which an English accoucheur had described and practised in 1860 required twenty-two years and a foreigner to bring it into vogue.

These accoucheurs treated two hundred and thirty-six cases with eight maternal deaths, a mortality of 3.3 per cent. Behm delivered fifty-eight cases consecutively, without a single maternal death. It must be remarked that Hofmeier and Behm treated all their patients themselves, whereas Lomer's cases were treated by nine different assistants. The presence of a skilled operator must of course be discounted in comparing ancient with modern methods, and so must the use of antiseptics. Still, it may be safely said that, after all due allowance is made, the above results have never been nearly reached. The reduction of mortality may be stated as from twenty-four per cent. to three per cent. The method may be described as—*a*. Bipolar podalic version as early as possible. *b*. Extraction by natural forces, or after complete spontaneous dilatation.

It is found, as said above, that the bleeding practically ceases after version and before extraction. As regards the life of the child, delay does not, according to statistics, much impair its chances, which are always bad; and, on the other hand, the great danger of laceration and fatal hemorrhage from it is set aside, while a fertile source of sepsis is also avoided. Other methods are still mentioned in text-books: complete or partial separation of the placenta, rupture of the membranes, and plugging. Rupture of the membranes and evacuation of the liquor amnii is often impossible when the placenta is completely prævia; the other methods have no such brilliant results, and must predispose to sepsis by the fingering of the placental site, and the retention of clots near it which they entail.

In France the use of the plug still holds its own, and the statistics have certainly improved since the introduction of antiseptics. Still, it can show no results like the above, and should not, in our opinion, be the routine practice among medical men. It must, however, be remembered that placenta prævia is one of the conditions which midwives often have to treat, at least temporarily in the ab-

sence of the doctor, and that unless these cases are treated properly they die. It is obviously impossible to intrust midwives, on the other hand, with so delicate an operation as bipolar version. For midwives the best treatment will certainly be to plug tightly with antiseptic precautions, washing out the vagina, and plugging, if possible through a speculum, with cotton-wool or gauze rendered aseptic. There is nothing better for plugging than a bandage of corrosive sublimate gauze. The plug excites contractions, controls hemorrhage to a considerable extent (for concealed hemorrhage in placenta prævia is almost unknown), and preserves the membranes for turning by the accoucheur.

In summing up the question of treatment, it must be remembered that cases divide themselves into two principal classes: The first, in which the uterus, so to say, takes matters into its own hands and acts powerfully; in these cases, to temporize and assist labor, as by forceps or rupture of the membranes if they present, will often be sufficient. The second, in which the labor is disordered, the uterus demoralized, and, unless prompt and skilful help is at hand, the tendency is to rapid death. It is these cases about which there should be no two minds with regard to treatment, and it seems to be proved that it may be summed up as (*a*) bipolar version as early as possible, (*b*) extraction actually or practically left to nature.

There is yet a third class of cases, namely, that in which the patient is either moribund or in extreme and urgent peril from flooding, and in which forced delivery by manual dilatation affords the only chance. These cases are exceptional, and it is hardly necessary to add that the operation should be performed with all possible skill and gentleness.

There are several morals to be deduced from the history of placenta prævia. Firstly, the new is not always the true, nor the truth new. The latest improvement may be a retrograde movement, and the "greatest modern triumph" a thing of which the not remote future will be ashamed. We need not illustrate this maxim here; it is a text on which we have preached and shall preach again. To the reader we need only say, in the language of Sir Christopher Wren's epitaph (slightly altered), "*Si documentum requiris, circumspecte.*" The verdict of the day is often wrong; each must make up his mind as to what is bad and false and what is good and true. To follow fashion may entail forty (or twenty-two) years' wandering in the wilder-

ness, till it takes a foreigner to conduct us into the promised land. Secondly, it seems possible that even the most intelligent foreigners may fail to understand plain English and decry a practice which they fail to comprehend. In this instance it took twenty-two years for them to comprehend it. Thirdly, English practice is not always the worst, even if unacceptable on the Continent.

It will be seen that the best modern practice agrees with Dr. Braxton Hicks's recommendations in 1860, and that though some of the facts in the pathology of placenta prævia (such as the arrest of hemorrhage after turning and before extraction) were unknown to him at that time, as well as to his contemporaries, his name deserves a prominent place in the history of the affection.

A CASE OF POISONING BY DUBOISINE.

As cases of poisoning by duboisine are somewhat rare, we reproduce the following report by MR. CHARLES M. CHADWICK in the *British Medical Journal* for February 12, 1887 :

On July 13, at 11 A.M., H. J. H., aged 75, consulted Mr. T. Pridgin Teale with reference to his eyes. H. J. H. is suffering from slow-forming senile cataract, and on several occasions atropine has been used for purposes of examination. On this occasion, however, two disks, each containing $\frac{1}{100}$ of a grain of sulphate of duboisine, were placed in the eyes. Very shortly afterwards, patient complained of slight giddiness, became very fidgety, and was advised to remain sitting. In about twenty minutes, the pupils being fairly but not fully dilated, the necessary examination took place, H. J. H. standing during the proceeding. A few minutes later, he experienced a decided feeling of weakness and loss of control over the legs, great dryness of mouth, with exceedingly bitter taste. Fancying, however, the fresh air would do him good, he refused to remain, and elected to walk home. He had not gone far before it was evident that persons in the street regarded him as decidedly "under the influence of liquor;" his speech became husky and indistinct; he walked, talked, and behaved like one slightly intoxicated. Later, when at home, the symptoms progressed; complete inability to stand without assistance, or to recognize the position of objects, partly due, no doubt, to paralysis of accommodation, but also due to visual hallucination. For example, the patient would suddenly sit on the ground, imagining a chair was ready to receive him; drop a glass in

mid-air instead of placing it on the table; and grasp in the air above his head for his watch which had been taken from him. With difficulty he was got to bed, constant attendance being necessary to keep him quiet; there was incessant movement, with carphology, a suspicious way of glancing beneath the bed-clothes and behind the back. A few moments, when left to himself, sufficed for the whole room to be upset; towels, brushes, and shoes were placed in the bed, and boots on the dressing-table; this entertainment ended by a somewhat severe fall on the floor, whence he was unable to raise himself without assistance.

This incessant activity was accompanied by a flow of words, sentences strung together without any apparent connection, a return of memory to things which happened years ago; throughout, an air of fun and humor, the symptoms those of childishness rather than any attempt at violence.

The pulse was slow; the patient, entirely ignorant of what was the matter with him, imagined it was quite dark, whereas it was a bright summer afternoon. Four hours after the commencement, a small injection of morphine was given, and the patient became quieter, dozing apparently for a few seconds at a time. Three hours later he obtained an hour's quiet sleep, and, after some light nourishment, three hours' sleep, after which his mind appeared quite clear again. He was entirely unconscious of all that had passed; a feeling of weight in the head and general upset lasted for several days. The urine, before and after, was normal. The thoughts which such a case as this gives rise to are shortly these: It is known that children bear belladonna better than adults. Do advancing years gradually increase the susceptibility? Eight cases reported by Mr. Nettleship in 1879 would appear to indicate this. Secondly, was the poison absorbed entirely by the conjunctival mucous membrane? The bitter taste in the mouth might possibly be due to a referred sensation. Thirdly, does this susceptibility in old age point to an unpronounced pathological condition, which is liable to result, after a time, in that condition of atrophy and degeneration which is popularly known as "softening of the brain"? And, fourthly, does belladonna-poisoning, which resembles so closely acute alcoholism and post-epileptic delirium in most of its symptoms, ever give rise to those outbursts of violence,—so frequently destructive to life, and so invariably succeeded by entire ignorance of a deed, perhaps of the ghastliest de-

scription,—which render the medico-legal aspect of many so-called criminal cases so profoundly interesting?

POISONING BY HERRING-ROE.

In *La France Médicale* a case is related in which a man was poisoned by eating three hard-roed herrings. The symptoms were a feeling of oppression, vomiting, burning sensation in the œsophagus and stomach, very violent abdominal pains, and dysentery. The attack lasted about forty-eight hours, and could be traced only to the herrings. Cases of this kind are by no means rare. It has long been known that caviare (sturgeon-roe), and the ova of pike, barbel, perch, and other fish, have frequently given rise to symptoms of poisoning in Russia. M. Goertz, a Russian physician, treated three cases of this kind in one family; the patients had eaten hard roe, while the other members of the family who ate the soft roe experienced no inconvenience. Dr. Münchemeier, of Munich, in 1875 reported three cases of poisoning after eating barbel-roe. These cases, which were very severe, were treated with ice and tincture of opium and saffron. Professor Naunyn reported a similar case in Berlin in 1884. Among the numerous cases reported in Russia, herrings appear to have been the cause in only one. According to Huselmann, accidents of this nature, due to caviare of bad quality, are frequent and sometimes fatal among the poorer classes in Russia. It is impossible, according to him, to say exactly what the poisonous element is, and in these cases, as in poisoning by mussels, oysters, and other fish, the idiosyncrasy of the individual must be taken into account.—*The British Medical Journal*, February 12, 1887.

CONVULSIONS FROM IMPACTED FÆCES IN A YOUNG CHILD.

DR. G. W. SQUIRES, of East Avon, N. Y., writes as follows (*The Medical Record*, February 26, 1887):

On the 15th I was hastily summoned to see a little girl 11 months old, who, the messenger said, was dying in a fit. On my arrival I found the child just recovered from a convulsion, but there was twitching of the muscles and every indication of more convulsions. The thumbs were flexed in the palms; the eyes were wild and squinting. Upon examination I found the abdomen greatly distended, with hard, knotty-looking lumps,

which were readily recognized as being in the bowels. The mother made the remark that the child had been "terribly constipated;" that she had given her as much as three teaspoonfuls of castor oil without a movement of the bowels; that she had been in the habit of feeding her on potatoes, cabbage, bread, and, in fact, everything she ate herself. Every few minutes the child would cry out and bend almost double. I at once ordered an injection of warm water and Castile soap, and in ten minutes the bowels moved, bringing away a great quantity of hardened scybala the size of hickory-nuts. The child immediately felt relieved, and soon went to sleep. At the end of an hour she started up with another violent griping pain. Another injection was immediately given, bringing away more fæces covered with mucus. A few grains of comp. licorice powder was given, and the injections were repeated seven times, each time bringing away less hardened dejections, until the last was of quite natural consistency. The fever-thirst and convulsive symptoms disappeared as if by magic, the child asked for playthings, and was more bright and cheerful than it had been for weeks. The mother told me that the night before the convulsion the child had a severe attack of croup, which was undoubtedly of reflex origin. J.

NEW REACTIONS FOR KAIRIN, ANTI-PYRIN, AND ANTIFEBRIN.

KOHN, in *Rundschau* (Prag), gives some new reactions for kairin, antipyrin, and antifebrin. A few drops of solution of chloride of iron added to a dilute aqueous solution of kairin produces a violet color, which suddenly changes to brown.

Antipyrin.—1. Chloride of iron changes an aqueous solution, 1 to 100,000, to red. 2. A solution 1 to 100,000 turns blue-green when nitrous acid is added. Concentrated solutions furnish green crystals.

Antifebrin.—This gives no reaction with reagents mentioned. It is decomposed by boiling with solution of potassium, is tested for anilin, and after distilling this off is tested for acetate of potassium.—*National Druggist*, March 4, 1887.

THE attention of readers of Dr. Wood's article "On Bergeon's Method of Treating Phthisis" is directed to the advertisements of Whitall, Tatum & Co. and J. W. Queen & Co. We believe the apparatus made by either of these firms will be found to be satisfactory.

THE MODERN ANTIPYRETICS.*

BY PETER J. MARTIN, M.D., EASTON, PA.
(From the private laboratory of Dr. Ott.)

THE modern antipyretics are kairin, thallin, antipyrin, hydrochinon, and antifebrin. In this paper I shall consider all except the last. Kairin is obtained from chinolin by a process of hydration, oxidation, and substitution. Thallin was discovered by Skrap, of

Vienna, and so named because the salts of hydroparachin anisol ($C_{10}H_{15}NO$) were colored green by ferric chloride. Antipyrin belongs to a series of bodies (according to Dr. Knorr, of Erlangen) which he calls quinizine or dimethyloxy-quinizine.

In making these experiments it was the aim to determine how the antipyretics acted upon the phenomena of fever, whether through increased heat-dissipation or through lessened production. Hydrochinon, one of the drugs used, being comparatively a new antipyretic and not having been investigated to any extent, was first tried. Some experiments upon the lower animals were made to determine more accurately its general action before calorimetrical investigations were begun.

* This thesis was awarded one-half of the "Medical News Prize," of the University of Pennsylvania, 1887.

NERVOUS SYSTEM.

Experiment 1.—3.30 P.M., a medium-sized frog received subcutaneously .008 gramme in powder form. 3.46 P.M., some slight convulsive movements. 3.45 P.M., convulsions have become marked; they gradually extended over the whole body; animal is unable to move; loss of power in the anterior extremities, followed soon by loss of motion in posterior extremities; lies flat on abdomen, with the anterior extremities doubled under him, the posterior extended. 4.15 P.M., chest opened; heart beating normally. Twitching of muscles continued for some time after the animal was apparently dead.

Experiment 2.—3 P.M., frog received .004 gramme of hydrochinon subcutaneously. 3.05 P.M., signs of weakness in the posterior extremities; slight convulsive movements. 3.07 P.M., loss of power in the anterior extremities. 3.08 P.M., marked convulsions. 3.25 P.M., chest opened; heart beating 50 per minute.

Experiment 3.—Small frog; had left leg ligatured, leaving sciatic free, which was kept moist. 2.20 P.M., injected subcutaneously .015 gramme of hydrochinon. 2.22 P.M., convulsions very marked. 2.23 P.M., respiration and convulsions have disappeared; chest opened; heart beating 48 per minute.

Experiment 4.—Frog received at 2.53 P.M. .0005 gramme; no effect. 3 P.M., .0015 gramme injected. 3.05 P.M., some convulsive movements, especially when touched or disturbed in any way; frog recovered from the effect of the drug after a short time. 3.32 P.M., injected .008 gramme of hydrochinon. 3.35 P.M., convulsive movements and partial loss of power in the anterior extremities. 3.38 P.M., convulsions very marked. 4.10 P.M., chest opened; heart beating 36 per minute.

Experiment 5.—Frog; had left leg ligatured, excepting the sciatic nerve. 1 P.M., injected .012 gramme of hydrochinon. 1.05 P.M., convulsions present; loss of power over anterior extremities. 1.12 P.M., same amount of anæsthesia in both posterior extremities; sulphuric acid when applied does not cause reflex movements. 1.15 P.M., spinal cord divided at the medulla oblongata; convulsions still continued. 1.40 P.M., convulsions ceased; animal dead.

These experiments seem to show that small doses of hydrochinon produce convulsions and loss of power, which takes place first in the anterior extremities. The heart is not much affected. The convulsions are not cerebral, as they continue after section of the cord. The

want of sensibility is not due to any action upon the peripheral endings of the sensory nerves, but is caused by a central change.

Experiment 6.—Frog; had his left leg ligated, excluding the sciatic. 10.10 A.M., injected .02 gramme of hydrochinon subcutaneously. 10.14 A.M., convulsions; loss of power takes place first in the anterior extremities; tries to jump away, but only shoves himself a few inches on his abdomen; later on is unable to move; complete loss of power. 10.35 A.M., electric stimulus applied to the unprotected foot causes a very slight contraction of it, while in the protected foot there is a marked contraction. The muscle in the poisoned leg loses its irritability quicker than in the protected leg.

Experiment 7.—Large frog; had all the tissues of the left leg ligated, excluding the sciatic. 1.20 P.M., injection of .05 gramme of hydrochinon. 1.23 P.M., loss of power in the anterior extremities; violent convulsions and then complete loss of power; lies flat on abdomen; posterior extremities extended; the toes of the anterior extremities double under. 1.30 P.M., electrodes applied to the protected extremity cause marked contraction of the muscles; in the poisoned extremity the contractions were more feeble. Irritation of the poisoned foot caused no contraction in the protected leg, neither did irritation of any part of the body. 2 P.M., muscular contraction in protected extremity ensued with DuBois coil at 21 centimetres, while in poisoned leg it took place at 12 centimetres. Irritation of either sciatic caused muscular contraction.

Experiment 8.—Large frog; had tissues of left leg ligated, excluding the sciatic. 9.30 A.M., injected subcutaneously .07 gramme of hydrochinon. 9.33 A.M., convulsions; loss of power in the extremities. 9.35 A.M., complete loss of power. 9.40 A.M., protected leg responds to electrical stimulus; both nerve and muscle being more irritable than the poisoned extremity. 9.55 A.M., right leg irritable with DuBois coil at 8; left leg irritable with DuBois coil at 15; nerve in right leg responds at 18, while left leg acts at 26. Pinching does not cause reflex movements in either posterior extremities.

Experiment 9.—Large frog, 2.37 P.M., received under the skin .12 gramme of hydrochinon. 2.39 P.M., loss of power; convulsions. 2.40 P.M., sciatic of right leg divided; the twitchings in the leg were arrested. The nerve and muscle of the left leg were tested by DuBois inductorium.

Time.	Nerve.	Muscle.
2.55 P.M.	30	14
3.10 "	30	13
3.25 "	30	12
3.40 "	30	8

If the frog was struck with the handle of the scalpel, it produced muscular twitchings. 3.55 P.M., the spinal cord was destroyed by a thrust, but striking frog afterwards produced no muscular twitchings.

These experiments demonstrate that while the muscular irritability decreases, that of the nerve does not. The convulsions are not due to any action of the drug upon the muscle.

Experiment 10.—Large frog, at 3.58 P.M., received subcutaneously .01 gramme of hydrochinon. 4.1 P.M., violent convulsions. 4.5 P.M., destroyed the spinal cord; the convulsions immediately ceased.

Experiments 5 and 10 show that the convulsions are due to an action upon the spinal cord.

REFLEX ACTION.

Experiment 11.—Cerebrum of the frog was ablated. Reflex action was tested by water slightly acidulated with sulphuric acid. The time the leg remained in the water was noted with a metronome beating 100 per minute.

Time. P.M.	Metronome beats.
2.01.	12
2.03. Injected .002 gramme of hydrochinon.	
2.06.	8
2.09.	10
2.12.	10
2.15.	12
2.21.	23
2.27.	34
2.33. Injected .002 gramme of hydrochinon. Convulsive movement.	
2.36.	30
2.39.	28
2.43. Did not respond.	

Experiment 14.—Medium-sized frog; spinal cord divided at junction with the medulla oblongata.

Time. P.M.	Metronome beats.
2.03.	12
2.05. Injected .002 gramme of hydrochinon.	
2.06.	8
2.09.	12
2.17. Touch produced convulsions.....	12
2.20.	18
2.26.	18
2.35. Did not respond.	

Experiment 15.—Conditions same as in Experiment 14.

Time. P.M.	Metronome beats.
2.07. Cord divided.	
2.38.	8
2.39. Injected .002 gramme of hydrochinon.	
2.52.	10
2.55.	6
2.58.	14
3.00.	20
3.06.	35
3.12. Did not respond.	

Experiment 16.—Cerebrum ablated in a frog.

Time. P.M.	Metronome beats.
2.05.	9
2.07. Injected .002 gramme of hydrochinon.	
2.13. Convulsions.....	20
2.15. Did not respond.	

Experiment 17.—Frog; condition same as in preceding experiment.

Time. P.M.	Metronome beats.
2.31.	8
2.32. Injected .002 gramme of hydrochinon.	
2.42.	20
2.48. Did not respond.	

These experiments go to prove that hydrochinon lessens reflex activity by an action on the spinal cord, for the same results ensue after removal of Setschenow's moderating centres.

ACTION ON VOLUNTARY MUSCLE.

Experiment 18.—Frog received subcutaneously .004 gramme of hydrochinon at 2.20 P.M. 2.26 P.M., convulsive movements; spinal cord and brain destroyed. 2.30 P.M., gastrocnemius attached to lever of Marey's myograph, the load being ten grammes. The muscle was directly irritated by electrical stimulus, and the curves were registered on the smoked drum of a Marey-Foucault regulator. The time of contraction was noted by a tuning-fork registering 240 vibrations per second. Several experiments showed a slight prolongation of the muscle-curve.

CIRCULATION.

Experiment 18.—Frog; chest opened.

Time. P.M.	Heart-beats per minute.
2.14. Injected .001 gramme of hydrochinon	26
2.25.	20
2.29.	17
2.32.	14
2.35.	11
2.41.	10
2.50.	9
3.50.	7

Experiment 19.—Frog received .0015 gramme of atropin subcutaneously.

Time. P.M.	Heart-beats per minute.
1.59.	20
2.00. Injected .01 gramme of hydrochinon.	
2.10.	20
2.15.	18
2.20.	18
2.35.	16
2.45. Acting feebly.....	14
3.45.	14

These experiments, with several others, proved that hydrochinon affects the heart by lessening the number of beats ; also the force of the heart. Injection of atropin does not alter the results.

Experiment 20.—Cat etherized ; carotid and jugular prepared. Ludwig's kymographion used.

Time. P.M.	Pulse.	Pressure.	Remarks.
2.0	57	96	
2.0.15	49	102	Injection of .004 gramme of hydrochinon.
2.0.30	51	108	
2.1	46	112	
2.2	55	108	
2.5.30	59	152

3.31.45	73	64	
3.4504 gramme of hydrochinon.
4.01.15	77	70	Animal killed.

The preceding experiments prove that small doses in the cat increase the arterial tension and do not affect the pulse. Large doses increase the pulse and pressure, followed by a depression of both. After paralysis by atropin of the vagi, the pulse rises and subsequently falls as before, showing that peripheral cardio-inhibitory action is not affected.

Experiment 25.—Large cat ; all the cardiac nerves in the neck divided ; cord divided at the atlas verified by a post-mortem, tracheotomy, and artificial respiration.

Time. P.M.	Pulse.	Pressure.	Remarks.
2.30.30	60	98	
2.30.45	62	100	.04 gramme.
2.31	68	98	
2.32	65	100	Injected .04 gramme.
2.32.15	64	108	
2.32.45	64	100	
2.34.15	...	98	

This experiment shows that hydrochinon only slightly increases the pressure, which increase lasts only a short period. The conclusion follows that the rise and fall of pressure are due to the action of the drug upon the main vaso-motor centre and the heart.

RESPIRATION.

Experiment 26.—Rabbit; tracheal canula attached to Marey's polygraph; jugular prepared.

Time. P.M.	Respiration.	Remarks.

2.55	13	.02 gramme.
2.55.15	27	Struggling.
2.30.45	6	Animal killed.

These experiments show that hydrochinon increases the respiratory movements. Section of the vagi does not alter the result. The increase of respiratory action is due to an excitation of the respiratory centres.

CALORIMETRICAL EXPERIMENTS.

In the following experiments the skull of the animal was trephined in the median line from a point back of the posterior angle of the eye. The animal was firmly secured, so as to avoid the possibility of making a large lesion through the slipping of the trephine. A puncture was then made with a small spear-pointed instrument, whose point was two millimetres in width and the body of the instrument one millimetre in diameter. The object of the puncture was to destroy the centre inhibiting heat,* discovered by Dr. Ott to be about the corpora striata. There are three points which, when punctured, produce heat,—(1) the tissues about the corpus striatum, the nodus cursorius; (2) the anterior end of the thalamus; and (3) the point between the thalamus and corpus striatum, which Schiff has pointed out as causing in rabbits a peculiar

cry when injured. Dr. Ott also has shown that the increase of temperature was due to increased production of heat. After the operation the animal was kept in a room until a sufficient rise of temperature ensued. If the first puncture was not successful in producing fever, the operation was repeated till the inhibiting heat-centre was injured. The animal was then transferred to D'Arsonval's calorimeter, surrounded by felt and feathers. The temperature of the calorimeter was kept a little below that of the room. The air was aspirated from the calorimeter by means of Voit's respiration apparatus, the large meter here being run by an overshot water-wheel. The temperatures are Fahrenheit in the following experiments. The thermometers were corrected at the Yale Observatory. The calculations were made in the manner published elsewhere. In all the experiments the temperature of the room and the calorimeter were kept as nearly as possible the same. In a series of experiments it was found that for every degree the calorimeter stood below that of the air, it was necessary to deduct $\frac{1}{100}^{\circ}$ F., as normally the calorimeter rose this much in the warmer air of the room. Lately the correction has been reduced to $\frac{1}{1000}^{\circ}$ F. In all the experiments the watery solution of the drug was used and injected subcutaneously.

CALORIMETER EXPERIMENTS—HYDROCHINON.

* *Journal of Nervous Diseases*, 1884 and March, 1887.

$V + (V \times t \times .00035) = V'$
 $V' = 2840 \text{ litres} \times 61.028 \text{ cu. in.} = 173319.5 \div 1728 = 100.3 \text{ cu. ft.}$
 $t' = 79.9 - 32^\circ = 47.9 \times .00035 = .0974$
 $V + .0974 V = 100.3 \text{ cu. ft.}$
 $V = \frac{100.3}{1.0974} = 91.4 \text{ cu. ft. at } 32^\circ \text{ F.}$
 $W = 91.4 \times .08073 = 7.39 \text{ lbs.} = \text{wt. of air.}$
 $Q = W \times t \times \text{sp. h.}$
 $7.39 \times 2.3 \times .2374 = 4.03 = \text{heat fr. air.}$
 $37.5 \text{ lbs.} = \text{wt. of water in calorimeter.}$
 $37.5 \times 1 \times 1.008 = 37.51 \text{ heat units to raise water } 10^\circ \text{ F.}$
 $43.5 \text{ lbs.} = \text{wt. of copper in calorimeter.}$
 $43.5 \times 1 \times .095 = 4.13 = \text{heat to raise copper } 1^\circ \text{ F.}$
 $37.57 + 4.73 = 42.30 = \text{heat required to raise calorimeter } 1^\circ \text{ F.}$
 $42.30 \times (9 - 3 \text{ correction}) = 25.03 = \text{heat to calorimeter.}$
 $25.03 = \text{heat to calorimeter.}$
 $4.03 = \text{heat taken from air.}$
 $21.00 = \text{heat dissipation.}$

After giving drug :

$V' = 3759 \text{ litres} \times 61.028 \text{ cu. in.} = 229404.2 \div 1728 = 132.2$
 $t' = 79.6^\circ - 32^\circ = 47.6 \times .00035 = .0969$
 $V + .0969 V = 132.2 \text{ cu. ft.}$
 $V = \frac{132.2}{1.0969} = 120.4 \text{ cu. ft. at } 32^\circ \text{ F.}$
 $W = 120.4 \times .08073 = 9.71 \text{ lbs.} = \text{wt. of air.}$
 $Q = W \times t \times \text{sp. h.}$
 $9.71 \times 5.1 \times .2374 = 17.99 = \text{heat fr. air.}$
 $41.78 \times (1.4 - .4) = 41.72 = \text{heat to calorimeter.}$
 $17.99 = \text{heat from air.}$
 $23.73 = \text{hourly dissipation.}$

HEAT PRODUCTION.

$Q = W \times t \times \text{sp. h.}$ $W = 3.4 \text{ lbs.}$
 $\text{Loss of temperature per hour, } 2^\circ; \text{ sp. h. } .83.$
 $3.4 \times 2 \times .83 = 5.66 = \text{heat taken from reserve.}$
 $21.00 = \text{heat dissipation.}$
 $5.66 = \text{heat taken from reserve.}$
 $15.34 = \text{hourly production.}$

After giving drug :

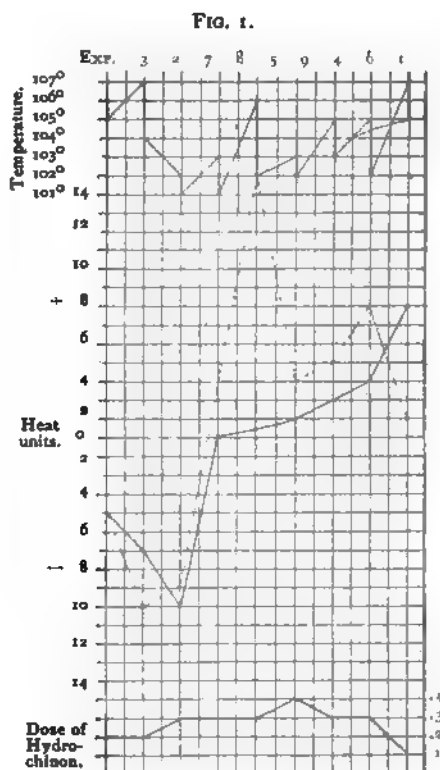

No change of temperature; hourly dissipation 23.73 = hourly production

	Heat dissipation.		Heat production.			
	Before drug.	After drug.	Before drug.	After drug.		
	R. T.	R. T.	R. T.	R. T.		
1.	21.00	107-105	21.73	15.34	105½-105½	23.73
2.	12.64	107½-106½	2.43	10.15	104-104	2.43
3.	6.17	106½-106½	1.15	6.17	105½-105½	.61
4.	17.98	105-104½	23.20	16.91	104½-103	20.81
5.	15.98	106-106½	25.64	16.64	104-101.7	18.07
6.	1.13	105½-105½	9.14	1.57	105½-108	5.59
7.	21.74	102½-102½	14.46	20.34	102½-100.4	9.50
8.	9.47	103½-102½	13.50	8.57	102-100.0	9.83
9.	14.66	103½-103½	18.94	14.66	103½-102½	16.80

The above results give a tabulation of the experiments with hydrochinon for one hour before the subcutaneous injection of the drug and one hour after. The animal was put in the calorimeter at periods varying from a quarter of an hour to an hour after the administration of the drug.

Dose.	Heat production.	Heat dissipation.	No. of exp.
.2	- 5.56	- 5.02	3
.2	- 7.72	- 10.21	2
.3	- 10.78	- 7.28	7
.3	+ .66	+ 4.03	8
.3	+ 1.31	+ 17.66	5
.4	+ 2.14	+ 4.28	9
.3	+ 3.90	+ 5.22	4
.3	+ 4.02	+ 8.01	6
.1	+ 8.40	+ .73	1

The above table shows the dose of hydrochinon, the decrease or increase of heat production in each experiment, also the increase or decrease of heat dissipation. In Fig. 1 the

increase and decrease of units of heat production are expressed by curves. The dose is also shown by a curve, and also the changes of temperature during each experiment. The dotted line is always that of heat dissipation. Thus, in Experiment 3 the temperature fell from 106° to 105° ; the decrease of heat production was five units, and of heat dissipation the decrease was five. By following the line marked Experiment 3 down we find the dose to be .2 of a gramme. I should like to give all the experiments in detail, as in Experiment 1, but the calculations would only be tedious and monotonous.

In Experiment 1 there is an increase of heat dissipation and heat production in the period after administration of the drug. Here the production of heat is increased more than the dissipation. In Experiments 2 and 3 there was a decrease of dissipation and production; in Experiment 2 the decrease of dissipation was greater than that of production, while in Experiment 3 the decrease of both is small. In both these cases the decrease of production would have been greater had the animal

been transferred to the calorimeter within fifteen minutes after the administration of the drug. Subsequent experiments demonstrated that the drug commenced to act in ten to fifteen minutes after its injection subcutaneously. The remainder of the experiments—three are fevered animals and two are normal rabbits—show an increase of heat production and heat dissipation, the latter being much greater than the former. Hydrochinon generally in full doses causes increased production and increased dissipation, the latter being greater. By this means the temperature is lowered. Small doses at times also decrease heat production and heat dissipation.

Heat dissipation.	Heat production.	Heat dissipation.	Heat production.	No. of exp.
Before drug.		After drug.		
R. T.		R. T.		
19.94	103½-105½	19.82	105½-104	7.41 1
16.89	103½-103½	15.69	103½-108	13.62 2
14.03	104½-103½	11.93	103½-108½	18.87 3

13.52	107-107½	14.89	107½-104	11.83 6

The above numbers show the effects of antipyrin on heat production and heat dissipation; they show also the temperature changes.

ANTIPYRIN.

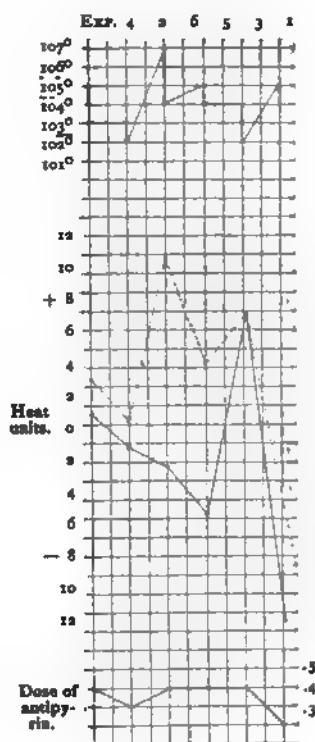

Dose.	Heat production.	Heat dissipation.	No. of exp.
.5	+ 1.43	+ 3.43	4
.4	— 2.08	+ .51	2
.5	— 3.06	+ 9.95	6
.5	— 5.96	+ 4.15	5
.5	+ 6.94	+ 6.94	3
.3	— 11.81	— 8.24	1

The above table shows the decrease and increase of heat units in heat production and dissipation; also the number of experiments and the dose of antipyrin.

The series of experiments with antipyrin show an increase of heat dissipation in all the experiments except one, where there is a decrease of the dissipation and production, the fall of the latter being much greater than the former. There is also a decrease of heat production in Experiments 2, 6, and 5. In Experiments 3 and 4 there is an increase of heat production and of dissipation, but the dissipation is increased more than the production. No spasms or convulsions were noted from the use of the drug.

Generally it may be said that antipyrin decreases heat production and increases heat dissipation, thus being an ideal antipyretic. Fig. 2 shows the results in a graphic manner.

FIG. 2.

.5	" 5 + 1.86			— 7.52	
.5	" 6 + 8.72			+ 4.05	

The above tables show the effects of thallin upon heat production and heat dissipation; also the variations of temperature. The second group of numbers exhibits the dose, the number of experiments, and the respective increase and decrease of heat production and heat dissipation by thallin.

The thallin experiments demonstrate an increased dissipation, while half show increased production and the other half diminished production. The increase of dissipation is much greater than that of production. These results prove that thallin reduces fever by increasing dissipation, while its effect upon heat production is variable even with the same dose.

Fig. 3 shows the changes delineated by curves.

FIG. 3.

KAIRIN.

+ 5.71	- 8.43	3
+ 8.58	- 7.85	4
+ 16.92	+ 16.32	5
+ 7.80	- .76	6
- 3.00	- 5.98	7

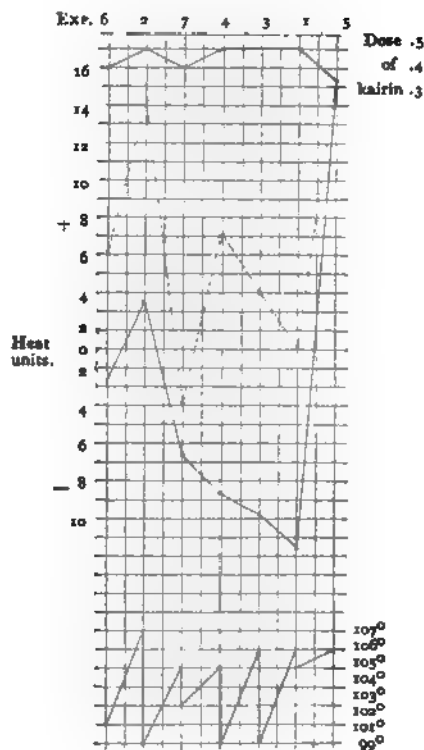

The above experiments are tabular statements of the effects of kairin on the heat phenomena, also the effects of the drug upon the temperature, the increase and decrease of heat production and dissipation. In the experiments with kairin heat dissipation was increased in all except one, where it was slightly diminished. Heat production was diminished in the majority of the experiments. This drug reduces temperature by decreasing heat production and increasing heat dissipation.

Fig. 4 illustrates the changes numerically given.

In reviewing these experiments with the antipyretics, it may be concluded that all increase heat dissipation, while their effect upon heat production is variable.

Why they should increase the production in one animal and diminish it in another, with the same or nearly the same dose, I

FIG. 4.

am unable to explain. The conditions surrounding the experiments were always the same.

It is true that I am dealing with a fever experimentally produced, a true nervous fever, where heat production is increased, and it is possible the drug was not able to retard the tendency to increment of heat production. No other effects were produced in the animals except (Experiment 1) where .5 gramme of kairin caused the animal to stagger, with loss of power in the legs. In the calorimeter convulsions appeared, and death ensued an hour and a half after the injection of the drug.

The figures show that there is no direct relation between the curve of temperature and that of heat production and that of heat dissipation. The curve of temperature is a resultant of the curves of heat production and dissipation. High temperature may be either the result of decreased or increased production and of decreased or increased dissipation. Thus, if heat production is decreased, heat dissipation may be decreased and the temperature be high, or heat production may be increased and heat dissipation decreased, also causing a high temperature. In the case of thallin the want of relation of the fever-curve to that of either heat production or of heat dissipation is well marked.

These experiments also demonstrate that as a rule heat production follows heat dissipation in its ups and downs, although the drugs sometimes reverse matters, as in the antipyrin series.

*AN EXPERIMENTAL INQUIRY INTO THE
CHEST MOVEMENTS OF THE
INDIAN FEMALE.**

BY THOS. J. MAYS, M.D. PHILADELPHIA, PA.

THE function of respiration is a very complicated act, but is principally carried on by the movements of the thorax and of the diaphragm. The former is chiefly supplied by the intercostal nerves, which arise from the thoracic portion of the spine; while the diaphragm is innervated by the phrenic nerve, which arises from the third and fourth cervical nerves. The diaphragm has an extensive range of motion, and during a maximum contraction it has the power of more than doubling the chest capacity, and is therefore the most essential factor in respiratory motion.

While, then, from a morphological point of view there is no doubt that the expansibility of the thorax is greatest in its longitudinal direction, Boerhaave† as long ago as 1744 observed that a fundamental difference existed between male and female respiration, that the abdominal or diaphragmatic breathing is most prominent in the male, and that the costal breathing is most marked in the female. The question of greatest interest to us here is whether this difference of respiratory motion is primitive, or whether it was acquired through influences such as are known to have modified other portions of the body. Hutchinson,‡ who likewise paid a great deal of attention to this subject, did not pretend to explain the cause of the variation, although he did not believe that it was caused by tight dress, because he found the same to exist in girls from twelve to fourteen years old who had never worn anything tight. He admits,

however, that it may be a peculiar "reservation against the period of gestation, when the abdomen cannot allow of so free a descent of the diaphragm."

It occurred to me that an observation on the respiratory movements of females of a wild race, who had never been subjected to the constriction produced by civilized dress, would assist in solving this problem, and I feel deeply indebted to the kindness of Mrs. J. Bellangee Cox, Mrs. Chas. F. Lennig, and Mrs. Thomas K. Conrad, directresses of the Lincoln Institution, for granting me the privilege of investigating the chest movements of the Indian girls in that school. This was done by means of a pneumograph devised by me somewhat after that of Paul Bert. The instrument consists of a pair of calipers with two long and two short arms. The long arms are applied to the chest and the short arms extend beyond the pinion which binds the instrument together. Between the two short arms and by means of two small pinions an air-drum is adjusted in such a way that the slightest motion produces either a rarefaction or a condensation of the air in the drum, which being connected by a column of air with a similar drum carrying a registering lever, the movements of the chest are accurately marked on a revolving cylinder. In order to produce a slight and uniform pressure on the walls of the chest, the two long arms are connected near their union by a thin piece of elastic rubber.

In all I examined the movements of eighty-two (82) chests, and in each case took an abdominal and a costal tracing. The girls were partly pure and partly mixed with white blood, and their ages ranged from between ten and twenty years. Thus there were thirty-three (33) full-blooded Indians, five (5) one-fourth, thirty-five (35) one-half, and two (2) were three-fourths white. Seventy-five (75) showed a decided abdominal type of breathing, three (3) a costal type, and three (3) in which both were about even. Those who showed the costal type, or a divergence from the abdominal type, came from the more civilized tribes, like the Mohawks and Chippewas, and were either one-half or three-fourths white; while in no single instance did a full-blooded Indian girl possess this type of breathing.

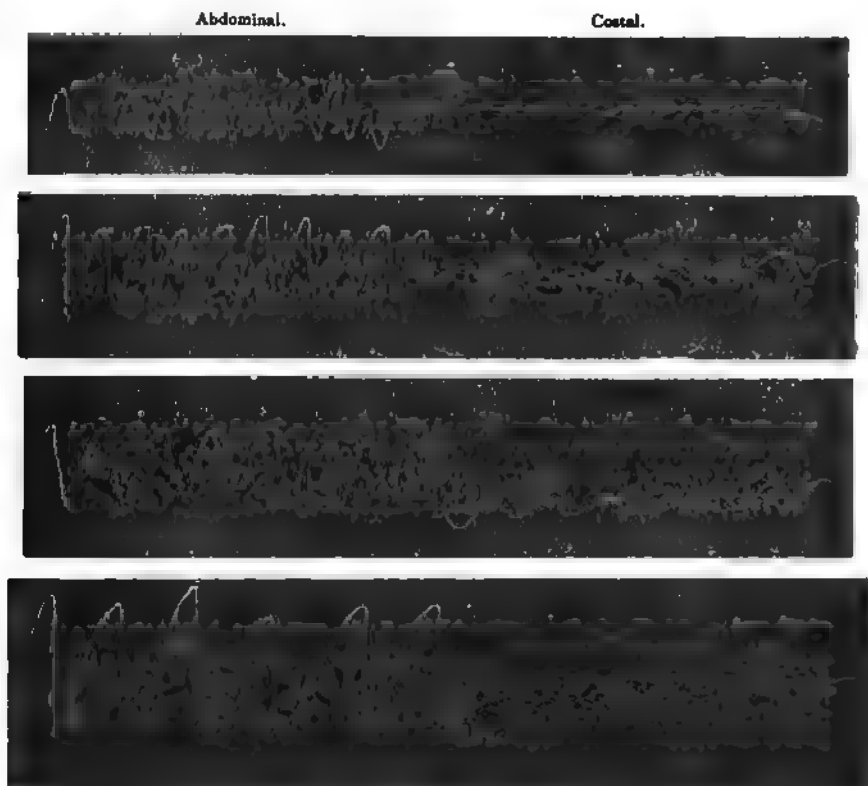

Below will be found four tracings which are characteristic of the abdominal type of breathing as compared with the costal breathing among the Indian girls at the Lincoln Institution:

* Read before the College of Physicians (Phila.), April 6, 1887.

† *Prælect. Acad.*, § 623, tom. v. p. 144. Ed. Haller, Amst., 1744.

‡ "Thorax," Todd's *Cyclopædia*, vol. iv., Part II., p. 1080, 1852.

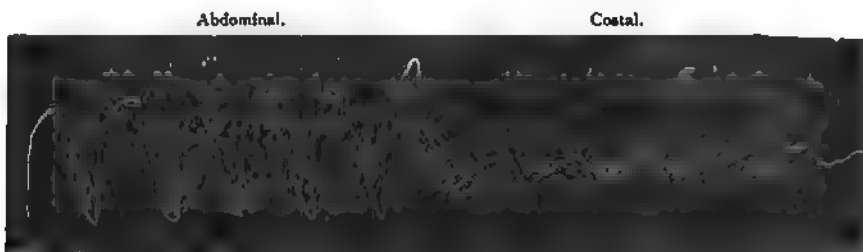

FIG. 1.—TRACINGS TAKEN FROM CHESTS OF INDIAN GIRLS.

For the sake of comparison I will append a tracing from the chest of a civilized male (adult), which bears a close analogy to those of the above

constriction could modify the movements of the thorax during respiration. At my first visit to the institution I obtained an exceptional costal type of respiration from a full-

FIG. 2.—TRACING TAKEN FROM CHEST OF A CIVILIZED MALE.

From these observations it obviously follows that, so far as the Indian is concerned, the abdominal is the original type of respiration in both male and female, and that the costal type in the civilized female developed through the constricting influence of dress around the abdomen. This is markedly shown in the greater prominence of the costal movements in those girls who were either one-half or three-fourths white, and who were hence dominated to a greater or less extent by the influence of civilized blood. While these tracings were taken an incident occurred which demonstrated that abdominal

blooded Indian girl. At my next visit I concluded to repeat this observation, and found that, contrary to my instructions concerning loose clothing, etc., this girl at my first visit had worn three tight belts around her abdomen. After these were removed she gave the abdominal type of breathing which is characteristic of nearly all the Indian girls.

It is also very evident that the costal type of respiration in the civilized female is not due to the influence of gestation, as was believed by Boerhaave, Haller, and Hutchinson; for the influence of this process obtains

as much among the uncivilized as it does among the civilized people, yet my observations fail to confirm such a view in the least.

What practical bearing, then, does an immobile thorax have on health and disease? In a former communication* on this subject I endeavored to show that one of the principal factors in the causation of pulmonary consumption is an inactivity, or a want of expansion of the upper portion of the lungs. Now, is the want of expansibility in the lungs of these Indian girls a mere coincidence, or is there a causal relation between it and pulmonary consumption? I think the existence of the latter relation is almost certain when we take into consideration the fact that the death-rate from this disease among those Indian tribes who have most recently come in contact with civilization, and from whom these school-children are chiefly obtained, is nearly double that of the white race. There is little doubt that the Indian in his native wild state is almost exempt from pulmonary disease, as is well attested by the history of those tribes who are living now as they have lived for three centuries or more, but his first contact with civilization surely disintegrates him. His habits and customs are entirely reversed. His life of physical activity, which was exclusively carried on in the open air, and which had a tendency to stimulate and to develop his respiratory organs, is now exchanged for the reservation, where he is housed and fed, his roving instincts checked, and where he soon sinks into a state of listless mental and physical apathy, and from which he readily merges into confirmed pulmonary disease.

Starting from these premises, our path of duty, when considered in relation to the prevention of pulmonary disease among these Indian children, lies straight before us, and this is in the direction of increasing their chest capacity. This can undoubtedly be best accomplished in the first place by daily inhalations of compressed air in accordance with the Waldenburg method; secondly, by gymnastic exercise, which is calculated to develop the muscles of the chest and of respiration; and, thirdly, by allowing them an abundant supply of fresh air both day and night.

One more point deserves attention. What is the influence of such abdominal constriction as is practised by our civilized female

on the respiratory function? Is it detrimental to health, or is it not? If, as is shown by my experiments, that interference with the motion of the diaphragm produces a compensatory breathing in the costal portion of the chest, does not this tend to antagonize or counteract the sluggish respiratory movement of the lung apices? Is there any intimate relation between this induction and the fact that proportionally, and as a rule not without some exceptions, a less number of females than males die of pulmonary consumption?

NOTE.—My warmest thanks are due to Mrs. Walters and Miss Pine, teachers at the Lincoln Institution, as well as to Drs. Burnett, Bliss, and Mr. Kyner, for their kind assistance in the prosecution of this work.

1716 CHESTNUT STREET.

RESULTS OF THE USE OF CASCARA SAGRADA IN FIFTY CASES.

BY M. H. FUSSELL, M.D., PHILADELPHIA, PA.

SINCE this drug was first brought prominently before the profession, the columns of our journals have been crowded with articles concerning it. I have been so firmly convinced of the great value of the drug as a laxative, however, that I do not hesitate to add to this already great number. During my term of service in the Medical Dispensary of the University of Pennsylvania we have used the drug largely in my room, almost to the exclusion of other laxatives.

I have selected these fifty cases because they were the longest under observation, and not because they all showed favorably to the drug. Indeed, I have taken care to include all the unfavorable cases whatever the time they were under observation. The preparation used in all cases was the fluid extract.

The beginning dose in all cases was gtt. xx t. d. Of the fifty cases the drug was useful in forty-three (43).

It entirely failed in seven (7).

In the forty-three favorable cases the dose of the drug was *diminished*, after using a longer or shorter time in twenty-nine (29) instances.

The original dose was continued in fourteen cases.

In *no* instance was it found necessary to *increase* the dose, which by trial was found sufficient to cause a daily evacuation of the bowels.

By referring to the summary of cases, it will be seen that when the drug failed the

Summary of Cases.

Case.	Age.	Disease.	Condition of bowels before use.	Time under observation.	Result.	Remarks.
1. Chas. Sherman.	...	Gastralgia.	Constipated.	1 month.	Bowels regulated; dose same at end of month.	Patient expressed himself as much relieved.
2. Jno. Miliken.	76	Chronic dyspepsia.	Constipated.	1 month.	Bowels regulated, and dose diminished.	
3. Jno. Kane.	60	Chronic dyspepsia.	Constipated.	4 months.	Bowels regulated; dose reduced. At end of time caused four daily passages.	
4. Pat Conly.	26	Lead-poisoning.	Constipated.	Bowels kept regular.	Patient did not return. This patient had not had a passage for years without monstrous doses of purgatives. Cascara was used only once daily at end of three months, and dose not increased.
5. Bridget Farrel.	35	Gastric catarrh.	Constipated.	Bowels regulated.	
6. Katie M.	19	Chlorosis.	Constipated.	1 week.	Bowels not opened.	
7. Mrs. C.	76	Cardiac disease.	Obstinate constipation.	3 months.	Bowels regulated daily. One dose taken at last.	
8. Mrs. W.	35	Stricture of rectum. (Syphilitic.)	Constipated; ribbon-feces. No passage for one week at a time.	1 year.	Bowels opened daily, but dose increased to $\frac{1}{2}$ t. d. This dose disagreed with stomach. Stopped, and in three weeks began again, gtt. xx, with excellent effect.	Under treatment the stricture relieved, and now bowels are regular.
9. Dinah C.	27	Tertiary syphilis.	Constipated.	2 months.	Bowels regulated; dose decreased.	At end of observation took the dose infrequently.
10. Fredericka H.	42	Migraine.	Constipated.	2½ months.	Bowels regulated; dose decreased.	
11. Jno. K.	23	Acute dyspepsia.	Constipated.	1 week.	Caused diarrhoea and griping.	Increased dose to gtt. xl t. d., and then decreased, and finally did without; had used large amounts of rhubarb, etc. After decreasing dose dispensed with medicine and had a daily stool. Finally took medicine every third day.
12. Ed. P.	...	Sciatica.	Chronic constipation.	1½ months.	Bowels regulated.	
13. Wm. G.	45	Chronic dyspepsia.	Constipated.	3 months.	Bowels regulated.	
14. Ella F.	20	Cardiac disease.	Constipated.	3 months.	Bowels regulated.	Had taken all sorts of purgatives; gss taken t. d. in beginning. This gradually reduced, and finally medicine discontinued and bowels regular.
15. Maggie M.	25	Chronic dyspepsia.	Constipated.	2 months.	Bowels regulated; decreased dose.	
16. Chas. R.	29	Chronic dyspepsia.	Constipated.	2½ weeks.	Bowels regulated; dose reduced; slight griping.	
17. Barbara S.	45	Malarial frontal neuralgia.	Constipation chronic.	1½ months.	Bowels regulated; dose diminished.	Had taken all kinds of purgatives; decreased dose.
18. John D.	50	Suspected Addison's disease.	Irregular.	1 week.	Bowels made almost uncontrollably loose.	
19. Peter D.	60	Chronic dyspepsia.	Constipated for years.	9 months.	Bowels regulated; dose decreased; medicine discontinued.	
20. Geo. K.	...	Lead-poisoning.	Constipated.	6 months.	Three stools daily; reduced dose, and bowels kept regular.	Had taken all sorts of purgatives; expressed himself as much pleased with the medicine.
21. Chas. T.	27	Neurasthenia.	Constipated.	1 month.	Bowels regulated; dose reduced.	
22. Edward C.	45	Gastric vertigo.	Constipated.	2 months.	Bowels regulated; dose reduced.	
23. Margaret M.	34	Flatulent dyspepsia.	Constipated.	1 month.	Bowels were kept open, but so much griping that medicine discontinued.	Had taken all kinds of purgatives; decreased dose.
24. Eugene C.	40	Chronic dyspepsia.	Constipated.	1 month.	Bowels regulated, but dose kept up.	
25. Mary S.	24	Gastralgia.	Constipated.	1 week.	Did not cause movement, but caused much griping.	
26. Peter B.	30	Chronic dyspepsia.	Constipated.	1 week.	Bowels not opened at end of week, but felt better.	Had taken all kinds of purgatives; decreased dose.
27. John D.	45	Chronic dyspepsia.	Constipated.	4 months.	3 t. d. caused two passages at first; at end of time caused four passages daily.	
28. John M.	...	Chronic dyspepsia.	Constipated.	2½ months.	Bowels regulated. At end of time had discontinued medicine and bowels were regular.	
29. Eliza C.	40	Anæmia.	Constipated.	1½ months.	Bowels regulated and dose reduced.	Had taken all sorts of purgatives. Expressed himself as much pleased with the medicine.
30. Michael B.	40	Migraine.	Constipated.	3 weeks.	Bowels regulated; dose reduced.	
31. Michael G.	45	Bronchitis; chronic constipation.	Constipated.	2 months.	Bowels regulated and dose reduced.	
32. James G.	61	Gastralgia.	Constipated.	1 month.	Bowels regulated; dose continued.	Had taken all kinds of purgatives; decreased dose.
33. Lewis Y.	51	Chronic dyspepsia.	Constipated.	1 month.	Bowels regulated; reduced dose.	
34. Leonard F.	...	Chronic constipation.	Constipated.	3 weeks.	Increased to gtt. xl, and acted well.	
35. James D.	20	Dyspepsia.	Constipated.	1 month.	Bowels regulated; medicine continued.	Had taken all kinds of purgatives; decreased dose.
36. Hugh Mc.	38	Bronchitis.	Constipated.	2 weeks.	Bowels regulated.	
37. May M.	60	Fatty heart.	Constipated.	6 months.	Bowels regulated; dose reduced.	

Summary of Cases.—Continued.

Case.	Age.	Disease.	Condition of bowels before use.	Time under observation.	Result.	Remarks.
38. John D.	31	Gastric ulcer.	Obstinate constipation.	5 months.	Bowels regulated; dose once a day.	
39. John H.	25	Acute dyspepsia.	Constipated.	1 month.	Acted irregularly; sometimes diarrhoea, sometimes no effect.	
40. Wm. C.	44	Chronic dyspepsia.	Constipated.	6 months.	Bowels regulated; dose discontinued.	
41. Sallie S.	27	Mitral disease.	Constipated.	3 months.	Bowels open only twice a week at first, after daily, and dose not increased.	
42. Mrs. S.	50	Chronic constipation.	Constipated.	4 months.	Bowels regulated; dose reduced.	
43. Miss L.	...	Chronic constipation.	Constipated.	2 weeks.	Bowels regulated; dose reduced.	
44. Mrs. F.	38	Neurasthenia.	Constipated.	6 months.	Bowels regulated by constant use; when medicine stopped bowels constipated.	
45. James M.	50	Chronic dyspepsia.	Obstinately constipated.	1 month.	5ii t. d. regulated bowels; after two weeks reduced to 5i.	This patient took fabulous doses of purgatives. Used to buy compound cathartic pills by the thousand.
46. Robt. R.	...	Costa. brach. neuralgia.	Constipated.	2½ weeks.	Bowels regulated.	
47. Mrs. C.	60	Carcinoma of stomach.	Constipated.	2 months.	Bowels regulated and dose stopped.	
48. Mrs. W.	73	Chronic constipation.	Constipated.	1 year.	Bowels regulated and dose only once daily.	
49. Lotta H.	23	Epilepsy.	Constipated.	6 months.	Bowels regulated; dose reduced.	
50. Mrs. D.	25	Chronic dyspepsia; pregnant.	Constipated.	2 months.	Bowels regulated, but so much griping that discontinued.	
51. Mrs. W.	50	Cardiac disease.	Constipated for years.	9 months.	Bowels regulated; dose not increased.	

cases were under observation for short times. The result might have been different if we could have kept the cases in sight.

It will also be noted that where the constipation was acute the drug did not act so well as where it was chronic. It was especially useful in long-standing constipation of older patients. Note especially Cases 2, 7, 13, 19, 27, 31, and 45.

The dose used (gtt. xx t. d.) was found to act better than a larger dose once daily. It did not cause griping, caused a more natural stool, and never disagreed with the stomach.

The results, as shown above, or in eighty-six per cent. of the cases, favorable, and over one-half, or fifty-eight per cent. of the cases, requiring the original dose to be diminished, while in no case was the efficient dose increased after prolonged use, justify the writer in recommending the trial of the drug in all cases of chronic constipation.

The bad taste of the fluid extract is somewhat of a drawback to its use in private practice. So far as my experience goes the various elixirs are about as nauseous as the extract.

In order to overcome this difficulty, Mr. Howard Levering, of Manayunk, prepared an abstract of the drug for me. He manipulated it much as he does the proper drug in making an abstract of jalap. In private practice I use this abstract of cascara sagrada in compressed

pills in doses of 3 to 5 grains, and find it quite as efficient and much more palatable than the fluid extract.

189 GREEN LANE, MANAYUNK.

CURIOSITIES OF THERAPEUTICS.

BY G. ARCHIE STOCKWELL, M.D., F.Z.S.,
PORT HURON, MICH.

I. PRIMITIVE AND PSYCHO-PHYSICAL MEDICINE.

(Concluded from page 237.)

IT has before been remarked that primitive peoples possess no knowledge of remedies or remedial effects in the sense understood by civilization. Yet, in the vicissitudes of nomadism (a mode of life that is far from inculcating economy or regard for the future), where there is no intermediate of feast or famine, there are times when whole tribes are brought to straits, and individuals seek anything in life or nature that promises subsistence. In this way some empirical information is occasionally obtained of substances that act as irritants and poisons, but such is soon lost or forgotten unless given to the *Shams*, who, by reason of a semi-priestly function, are the repositories of fact and tradition, treasuring the same as part of the mysteries

of the sacred lodge. Indeed, the trifling herbal knowledge some few tribes possess appears, for the most part, to have been derived from Romish missionaries,* most of whom possess some smattering of botany and pharmacy; and this little is of doubtful character, since the results obtained are never regarded as specific or substantive, but *reflective*,—i.e., the manifestations of the spirit with which the article is imbued. Nothing is understood of the relations of age, season, climate, or mode of gathering, to the growth; that the same herb or plant may be innocuous at one time and toxic at another, or depend for action upon the quantity employed; and should any failure result in an application, the fault lies not with the material, but its spirit, who is deemed inimical to the object, or friendly to that to which the object is directed. That poisons are often resorted to in order to satisfy personal ambition or pique is not to be denied, but their employment is by no means so frequent, or familiarity therewith so general, as is commonly surmised, and such are usually preparations of strychnine or arsenic, such as are procured from trappers and traders.

A writer, whose name I have forgotten, some years since gave to the public as the result of cursory observations among the savages of the northern frontier, an amount of information regarding the employment of toxics that forcibly recalls the days of Doctor Dee and the "Black Art," or the latter part of the sixteenth century, when poisons and

poisoners openly and shamelessly stalked abroad, penetrating hut, palace, and cloister alike, and the civilized world feared to eat, sleep, inhale odors and perfumes, or even approach the altar and holy font,—mysteries all that have long since been laid bare by chemical and physiological science. Two incidents upon which special stress is laid may be briefly summed up as follows:

An Otchipwe woman had all the muscles of the face paralyzed suddenly through the unknown machinations of a *medicine-man*, and, being of jolly disposition, her mirth was horrifying as being unaccompanied by expression.

Another, suffering with a painful wound of the hand, met a *Sham*, whose ill will she had unfortunately incurred, and who, under the guise of reconciliation, obtained possession of the injured member. He pressed it with such force and fervor as to arouse her suspicions, especially as the pain did not immediately abate. She imagined she saw or felt some foreign substance within his palm, and thereupon boldly accused him of an attempt to bewitch her. Angered by the persistency with which the charge was pressed, he finally admitted it, and announced henceforth, every year, when blackberries were ripe, she would become a *Sioux* †—a prediction that was literally fulfilled by an eruption of purple and black spots that, appearing in autumn, vanished with frost. ‡

* Familiar chiefly with the tribes of the Northwest border and of Mexico, I avail myself of the corroborative evidence of Rev. T. E. Ranney, who was for seventeen years a missionary among the Cherokees and Pawnees, which is briefly condensed as follows (*Archives of Science*, 1870): "They know as little of medicine as they do of religion, and nothing of either. They have no conception of the nature of disease or of the administration of medicine to affect the system, or of anything that would act as a cathartic, though they have learned from the whites that warm or tepid water provokes *emesis*. Bleeding and scarification are employed by the Otoes and Omahas as universal panaceas, but this knowledge is derived from civilization. Indeed, if the medical knowledge acquired from the whites was taken away there would be none left! The practice in accouchement is simply rattling a gourd,—a child's rattle. To remove fevers their *medicine-men* simply puff and blow at the patient with the mouth and practise jugglery; if he can eat he will live, if not he must die. One repeatedly encounters advertisements recommending medicines because they are used by the Indians, but they have no medicines. One of these is a Pawnee toothache cure, which is most absurd, as these people never suffer from diseases of the teeth." (This hardly corroborates the claims of McDade and his "Remedy.")

† "*Sioux*" means simply a "breaking out." Presumably the first Dacotah seen by an Otchipwe was suffering from some epidemic or eruptive disorder; hence the name applied to the former by the latter, and by both deemed a term of reproach. The Dacotahs term the Otchipwes *Hahatunwes*, or "People of the Falls," referring, doubtless, to the Ste. Marie's Rapids, which was once the headquarters of the tribe.

‡ Two Red River men, half-breed Crees, beat an Otchipwe *Sham*, not knowing him to be such, for stealing their clothes. The latter quickly announced his calling, and promised to "bewitch" them before the moon would again be full. A few days later they were discovered naked, wandering aimlessly about the open prairie, and violently insane; and, when seized, both fell into epileptiform convulsions, that in turn were succeeded by prolonged hypnosis, during which the persecutor was accurately described, even to dress, and the place in which he was then hiding,—and where he was subsequently apprehended. In time both recovered, but neither could ever touch spirits without a recurrence of epileptiform spasms. Personal inquiry revealed one to be a son of an epileptic father. The means said to have been employed in this conjuration was the burning of locks of hair obtained surreptitiously from the heads of the unfortunates while asleep; and it is surprising the number of people even of civilization who implicitly believe in this particular form of magic. (See Livingstone's "Expedition up the Zambesi," p. 53.) Again,

None of these cases are at all mysterious to those familiar with mental phenomena and the extreme nervous susceptibility of the savage; even more wonderful results sometimes accrue.* As a medical student I was privy to a practical joke, the outcome of a lecture on "Mental Impressions," played upon one of exceptional physique and health, and that confined the individual to his bed for the better part of a fortnight; and within a month I became cognizant of a like incident occurring among the clerks of a Chicago banking-house. Witness also the involuntary influence of a *Sham* upon a Scotch half-blood, renowned as a marksman, and remarkable for his exemplary Christian piety.

Wabijeshi, "The Marten,"—the *medicine-man* in question,—espying a particularly fine double gun presented to the half-breed by an English nobleman, picked it up, examining with great care, fingering the locks, and peering into the barrels. Shortly after the owner went out to hunt, but most unaccountably every shot sped wide of its mark. The day following he gave the gun a thorough cleansing and overhauling, satisfying himself it was in perfect order, yet his efforts remained unavailing. On trying the weapon at a mark his aim was found to be unerring, though he failed to bring down a single object. All this was most mysterious, and he fancied the gun "bewitched." Laying it aside for a borrowed weapon, he did not fail to slay every creature fired at, which served further to confirm his

by like supernatural means was encompassed the death of a prominent Mexican official. A Maya woman whom he had wronged grievously constructed a clay image, inscribing it with his name, and daily thrust hot needles therein. His disease baffled the physicians, and he died suddenly from excruciating pain in the heart,—his last words, "It goes through my heart." The hour of demise corresponded exactly with that when the Maya witch thrust a red-hot needle into the præcordial region of the image. In this instance the persecutrix had daily entrance to the dwelling of her foe, and was accustomed to stand at his bedside and threaten; and though the latter was a man of education, a graduate of the University of Guadalajara and the military school at Chapultepec, and a politician of note, the Aztec blood in his veins would not permit him to rise above inherent superstition.

* (See Supplement H.) Also I knew an Indian runner who lost his powers by the same means; and whereas he was before the *swiftest*, he now became the *slowest* of his tribe. The *medicine-man* professed to have entered his lodge during the former's absence and there "made *medicine*," and though subsequent events proved him an outrageous liar, and that he was fifty miles away at the time it was claimed the occurrence took place, the victim could not be convinced he had not in some way been bewitched; and he did not again recover his powers until the conjuror had been bribed to remove the spell.

suspicion. Upon *Waubijeshi's* return he was accused of violating hospitality and employing his supernatural powers to the detriment of a *friend*. The latter exhibited some surprise, but admitted "the spirits" might have taken an unknown advantage of him; whereupon, taking it again into his possession, he proceeded to exorcise the gun, after which it was proved to have recovered its wonted accuracy.†

The foregoing also illustrates the facility with which insensible and involuntary impressions may be communicated not only to other persons and to lower organisms,‡ but also to inanimate objects.§ It must be remembered that few even of the highest civilization are able wholly to divest themselves of the influences and impressions derived from inheritance and inculcated by early training; and the manifestations of the will are very far from *always* being the exact definition of the mind. That is to say, the mind is dual, and may at times respond more promptly to a forgotten and involuntary impulse than to one immediate and voluntary. Consequently a voluntary and perfectly unbiased decision where one's preferences are in question is all

† Here the fault manifestly was not with the gun, but the individual behind it, who, in spite of character and education, could not divest himself of the superstitions pertaining to his lineage as derived from an Indian mother, or of the reverence that ignorance always accords to those who deal with the mysterious, supernatural, and occult. He may have imagined the handling of the gun by the *Sham* produced no special impression upon his mind, yet the reverse is evident from his confession that *he narrowly watched the latter, fearing lest he might injure his treasure*. His suspicions could not but be aroused by evidences of curiosity in one who, by virtue of his calling, was supposed to *know everything*. It is also evident that for once the "*medicine-man's*" curiosity overcame the reserve peculiar to his profession.

‡ (See Supplement E.) Some Crees, jealous of the fame of a horse belonging to a neighboring tribe, and widely known as a racer and buffalo runner, employed a *Sham* to perform an incantation ("make *medicine*," to use the vernacular) that would divest the creature of its powers, which was done; the means professedly employed being the anointing of its legs with a mixture of deer's fat and hare's dung. The transaction was soon noised abroad, to the chagrin of the owners, as well as to their pecuniary loss, for the horse lost every race thereafter in which it was entered. Subsequently, on falling into the hands of a Hudson's Bay factor, a practical, hard-headed, non-superstitious Scot, the animal suddenly recovered all its former powers, securing to its new master a wide-spread reputation for *medicine*.

§ See articles in *Popular Science Monthly* for May and June, 1877, by Dr. William B. Carpenter, entitled "Mesmerism, Odyism, Table-turning, and Spiritualism."

but—if not quite—impossible. In such an instance, where an attempt is made to probe the motive, it is difficult to determine whether the verdict is a sequel to preferences or *fear of such* preferences.

It may provoke both mirth and comment, as coming from a member of the medical profession, when the assertion is made that marvellous cures do accrue to the conjurations and jugglery of *Shams*; yet it is none the less true. Though such are in a sense psychological, they are also physiological, as they depend upon the adaptability of the mind to receive and retain impressions. The savage, owing to surroundings and superstitions, is more susceptible to mental impressions than civilized man, and such are less apt to be associated with timid, ill-balanced, and disordered brains than is the case with the latter. I must confess, my own faith in therapeutic results does not rise superior to the consciousness that they are more frequently the sequel of indirect psychological phenomena in either the prescriber, or the one for whom prescribed, or *both*. I can vouch for two physicians, coequal in knowledge and ability, who derive widely different results from the same drug, even when exhibited under precisely parallel conditions and to the same individual; and I have procured all the idiosyncratic phenomena of a full dose of morphia by the exhibition of a black mustard-seed, mistaken in the twilight for the newly-made pill. I have known neuralgias, rheumatisms, fevers, dysenteries, diarrhœas, agues, paralyses, cystitis, etc., to be permanently relieved or benefited; tumors to disappear; convulsions controlled or produced; persons to become instantaneously stricken with blindness or palsy; rendered oblivious to pain and torture; deprived of muscular power and made rigid as marble; to drop as if dead, and pulseless; rise and walk when an instant before incapable of the slightest exertion; all by the conjurations and incantations of *medicine-men*. Also, I am personally conversant with the prediction of events in the far future exactly as they subsequently occurred, and with scrupulous fidelity as to details; the movements of persons and individuals to be described in minutæ who had never been seen, much less heard of, and who were hundreds of miles away at the time.* Moreover, I have witnessed feats of legerdemain, jugglery, and necromancy, exhibited in broad daylight under the full glare of the sun, as well as at

night, without paraphernalia or mystic aids, that would puzzle the most astute professor of civilized magic; some, to be sure, susceptible of explanation under physical and psychological laws, and others not so readily disposed of, save as optical and aural delusions and tricks of the imagination.†

Hypnotism is another branch of the savage conjuror's art, whereby certain nerve-sensibilities are temporarily paralyzed, either by mechanical or psychological process; and this, moreover, though natural to some, is readily acquired through the continued practice of *ecstasia*. It plays an important part in the relief of disease, and may even be carried to fatal results.‡

Call it all quackery if you will, yet the truth remains that the *medicine-man* does relieve suffering; that he is not an impostor in a civilized sense, since he is a firm believer in his own art, no matter what deceits may accompany it; and to him credit is due much more properly than to white charlatans, who, with even greater pretensions, set out to deceive, relying upon the varying chapter of incidents and accidents to cover their ignorance and secure the desired result.

Of course, common sense and *raison d'affin* have no place in primitive psycho-physical therapeutics, and no ideas obtain that are not crude, imperfect, and for the most part irrelevant. It is the implicit faith in the occult and mysterious that enables the savage to recover from disease promptly and readily, and the acuteness of nerve-organization, in this particular, is correspondingly blunted to the effects of *shock*.§ He is *not* better able to endure pain than the man of civilization; on the contrary, is more puerile under its infliction, and wont to give way upon trifling provocation when not sustained by hypnotism or *ecstasia*; but primarily and in the same ratio he is much less a sufferer mentally and physically,|| the result, doubtless, of his mode of life. Moreover, complete rest, while ill or suffering, accords perfectly with the natural indolence of his disposition.

† Supplements G and I.

‡ Vide Supplement H.

§ It is the testimony of all who have had experience among the Indian tribes that medicines, even in *half-doses*, affect them promptly.

|| Says Surgeon Hanson, U. S. Army, in a report to the Secretary of War upon the Indians of the Plains: "Their systems seem to possess comparatively little irritability or tendency to high grades of inflammation, and wounds heal with remarkable facility." Also, Surgeon David Mack, U. S. Navy, who is corroborated by Mr. J. G. Swan, says of the savages of the Northwest coast,

Noise and odor are the prime factors in the *armamentarium therapeuticum* of the primitive physician everywhere throughout the world,* modified only by individual taste and whims. Just as the ancients deemed the nose and ear the highways and emunctories of the brain, so the special senses of hearing and smell are associated with that of vision as the foundation of savage physiology; and all these are appealed to in the most emphatic and discursive manner on every occasion. It is no exaggeration to say I have known whole families, especially during the prevalence of some epidemic such as measles or smallpox, to be literally drummed, rattled, and *stank* out of existence. Just conceive of the "*Natural System of Medicine*" † that requires a patient to be confined in a close and stifling atmosphere, and submitted to combinations of sounds and smells calculated to drive the most obstreperous of foul devils to the remote confines of space,—odors so very infernal and nauseous that *even dogs are made ill thereby!* Can the absurdities of civilization go further?

When the *Sham* is summoned, in company with his assistants he proceeds to the couch of the invalid, and at once enters upon his jugglery without circumlocution. No examination is required to determine the cause or condition, since all maladies have like origin, and he possesses a never-failing means of defining the obtruding demon in the amulets that stuff his *medicine-bag* to repletion, and by which he can instantly summon before his mental vision the unseen denizens of the unknown. There is but one conclusion permissible: one or more demons have taken possession of the sufferer, or, perhaps, if the suffering is definite and pain circumscribed, the part is merely penetrated by the essences of some extraneous substances magically introduced, and that can be removed only by the same mysterious means. Objects professedly removed ‡ are sometimes exhibited, but there is seldom any pretence they are real, or that they serve any other purpose than is ascribed to the images of the Romish Church,—to *typically* bring

to the mental vision that which is supposed to be real.

If possible, the incantation is postponed until night, partly for personal reasons of the conjuror, and partly because the unseen and unknown are supposed to be more amenable to discipline after nightfall. It usually begins with a monotonous chant that rises and falls with abrupt inflections, wherein the demons are abjured to forsake the mortal clay and resume their own proper form, being alternately coaxed, humored, or threatened, as circumstances and their individuality warrant; also set songs are interspersed, the significance of which is not often understood outside of the mystic brotherhood.§ In the mean time a running accompaniment is kept up by means of drums and gourd and parchment rattles in the hands of the assistants.

By and by the songs wax louder and more violent, the drums are pounded harder and faster, the rattles shaken more vigorously and forcibly. Higher and higher the sounds rise, shriller and shriller the conjuror's voice is pitched, and faster and fiercer the accompaniment sounds, until the one becomes a frantic, piercing shriek, the other a pandemonium altogether fiendish, crazing, and excruciating beyond comprehension, until, finally, exhausted by his efforts, fairly black in the face, every pore streaming perspiration, the *Sham* pauses and—*eats*. A famished wolf is a miracle of satiety by comparison with his feats of gormandizing, which are ably seconded by all assembled.

Over and again this performance is repeated, while the smoke and fumes of burning gunpowder, fish-entrails, human and animal excreta, bones, hair, parchment, and fur fill the interior of the lodge to suffocation, procuring *stinks* that may fairly be *felt*; and during the interval the patient is blown upon with the breath,|| the painful parts sucked

§ One of these that I now recall appeared to be used for the purpose of flattering the spirit, and consisted in the constant repetition of the sentence,—

"Great-is-the-spirit-who-pervades-the-whole-world!"

each time in a different key with peculiar staccato rhythm, and marked jerking inflection upon the terminal word. Another is,—

"Great-is-He-who-walks!"

|| "After having been five days in Gömüshtepe I had a numerous levée of sick persons, or at least of men who pretended to be such, to whom I administered blessings and the *nefes* (holy breath)." (P. 73.) . . . "Touching—moving my lips as if in prayer—the suffering part of the body, and having thrice breathed upon her, a deep sigh is uttered. . . . Many in these cases persist they receive

"The nervous system is less active than with whites, as shown by insensibility to pain and the slight febrile symptoms that follow wounds, which heal readily."

‡ See page 309, also Supplement G.

with the lips, and sometimes even gashed with knives and flints, that *wet* cupping may be practised by exhausting the air through a bison horn with the lips.* At last, when the excessively tormented and vexed spirit is sufficiently placated or frightened, its exit is facilitated by a discharge of musketry through the lodges and round about to prevent its return; and this performance may be continued for hours after the *medicine-man* has retired.

A weak and mild demon may be gotten rid of with little trouble and ceremony, but an old and *seasoned* individual of varied accomplishments not infrequently demands the combined wisdom and powers of half a dozen or a dozen of the ablest conjurors, days, even weeks, being consumed ere a satisfactory (successful or fatal) issue is reached. Moreover, there are various creeds or articles of faith that are not wholly understood, and it is a mooted question whether by discipline the evil ones are coaxed or frightened from their victims, amenable to both measures, or susceptible of complete annihilation.

But the demon oftentimes does return in spite of all precaution. Relapse soon follows the subsidence of the incantations, or (physiologically speaking) with the termination of the nervous excitement and impression induced, requiring new efforts with the same vigorous application on each occasion, until Nature comes to the relief of the sufferer, or death intervenes and claims its victim. Unfavorable results matter little, and provoke no adverse comment, since the superstitions that attach to the *Sham* render him practically unassailable. It is to be expected that a demon of *standing* possessed of proper pride will endeavor to outwit the *medicine-man* and return with every opportunity, and the stronger and more persistent its manifestations the greater

instantaneous alleviation of their malady." (P. 164.) Again, he says, "The Mohammedan *moolahs* (priests) enjoy great respect from the reputation for mystery which attaches to their character, and which is the object of the dread of the superstitious nomads." (P. 359.)—Arminius Vamberg as a *moolah* in "Travels in Central Asia."

* The vapor-bath is not one of the prerogatives of the *medicine-man*, being resorted to by all indiscriminately without regard to condition or illness. It is merely a small lodge or wigwam, made by setting up a frame of twigs covered with bark, blankets, or skins, within which the individual seats himself, pouring water on heated stones. Urine is often added as a detergent to bathe the body and insure cleanliness, as it combines with the oily exudations of the skin, loosening the filth; and the ceremony is completed by a rush from the bath into the nearest cold pool.

evidence of ability on the part of the conjuror. Then there may have been a *new* spirit summoned to aid the old; or the *Supreme Manit* may have interfered because of some unfulfilled vow.† Anyway, it was *fate*, for the savage is as complete a believer and worshipper of *Kismet* as any Mussulman.

One peculiarity of the sick-lodge, must not be forgotten, and I commend it to the civilized Sangrado: the *Sham* must eat at every pause in his incantations, and that too upon the very best the surroundings afford, else he cannot sustain the courage and strength essential to struggles with the denizens of the unseen world; and it frequently happens that by this means not only the immediate family of the sufferer, but all his blood and *gens* relatives, are reduced from affluence to comparative penury.

Again, if a convocation—or consultation, if you like—of *Shams* is required, it is always summoned by, or in consonance with the wish of, the first one employed. This means the spirits are too strong or numerous for a single individual to cope with,—also more mouths to feed. The first affair of this kind I was permitted to witness occurred among the *Shaguan-da-gawin-ena* Otchipwes, and employed the talent of no less than a half-dozen *Shams*, and as many more novitiates. Gathered from remote distances and points wide apart, they rallied under the leadership of one famous in his day;‡ so much so that his reputation ex-

† A woman suffering from a simple tertian ague sought relief at the hands of the conjuror of her tribe. Every other day when the fever appeared the usual incantations were instituted, but with no permanent benefit. Finally the fellow availed himself of information obtained from a Hudson's Bay factor, who provided him with a number of powders of *quinine*, which were administered to the satisfaction of all parties concerned. But not, however, until the squaw had been mulcted of two handsomely-prepared and ornamented bison-robcs with which she heretofore had refused to part. Said he, "The cause of your trouble is a vow made many moons gone by. You dreamed that bison, moose, and wapiti were about you in great numbers; even hare and wild fowl came to the very door of your lodge; you knew it as an omen that you would no longer want. In gratitude you vowed a handsome robe; but robes were not then plenty, and you forgot. *Kitche-Manito* waited for you to redeem that vow; but as you did not, he became angry, and sent this evil spirit to torment you, graciously allowing one day to intervene that, if you would, you might remember your pledge. You will now appease him with your *two* best robes, one of which will be for the vow and one in propitiation for the delay. He will then permit me to give you a white spirit that will drive the evil one away. You will then become strong, renew your youth, marry again, and become the mother of many fine boys!"

‡ For some reason this individual, who was the son

tended far beyond the precincts of his tribe,—and when assembled a more grewsome and spookish crew it would be difficult to imagine outside of Pluto's own particular domain.*

The "big man" certainly deserved the distinction accorded him, if for no other reason than size and stature; he was by long odds the *largest* Indian I have ever seen, being above six feet in height and four hundred pounds weight. Gorgeously fagged out, he presented all the extremes of savage frippery and splendor, his costume being as *bizarre* as it was striking. From his shoulders hung a massive robe of black bears' skins, elaborately lined and trimmed with scarlet; fringed blue-cloth leggings, and tanned caribou-skin moccasins, both miracles of beaded and dyed porcupine-quill work, ornamented his nether extremities; paints of various colors and hues, green and vermilion predominating, and laid on with no niggard hand, marked his face and the naked flesh wherever exposed; an elegantly-wrought *medicine-bag* of mink-skin and a large silver medallion of Her Majesty Victoria hung suspended by broad ribbons from his neck; and decorations of toys in metal, glass, and wampum, and little bells were artistically displayed at every available point of his dress. To crown all, his head supported the skull of a wapiti stag, or Canadian elk, prepared in a wondrously life-like manner, and surmounted by an immense pair of antlers that nearly doubled his stature. Gurth's vision in Dreamland ne'er conceived so wild a "hunter."

His following all exhibited more or less originality in procuring the hideous and impressive. Ornaments and paint were distributed and arranged with a view to effect, and, as may be imagined, varying and bewildering results were obtained. One had his face completely hidden by transverse bars of vermilion and ochre, with a broad, oval patch of black encircling each eye; a second had daubed his with black, painting the orbits white,—a most ghastly masquerade; a third employed white and black in alternate horizontal bars, the eyes set in vermilion; another satisfied his vanity with plain ochre; and still another wore a wolf-skin robe, the head of the

of a renegade Blackfoot by an Otchipwe woman, preferred to be known by the *Mannikappi* designation of "*Pou-ni-ka-ma-ta*" ("Spirit Wapiti" or Elk), though in Otchipwe his name was rendered as "*Kitche-Mish-a-wak*" (the "Big Elk").

* This incident I reproduce from a paper of mine contributed to the *Popular Science Monthly* in September last.

creature serving as a cowl, that was drawn over the face. The novitiates and assistants, however, differed little from the laity save for *medicine-bags* and instruments, conspicuously displayed as badges of authority and calling.

The scene was night, just before the "witching hour," in a natural opening scarce thirty yards in diameter, beside the lake, hemmed in on three sides by towering red pines amidst stunted spruces, and fitfully illuminated by rays of the moon that straggled hither and thither through the tops. A small fire kindled in the centre only added to the gloominess of the surroundings, its beams serving to magnify the moving figures into ghastly shades and shadows that danced spectrally across the water or over the umbrageous foliage of an evergreen background. Everything tended to recall and impress the mysterious and supernatural.

The unfortunate in whose behalf the *medicine*† council had been called was a man just past the prime of life, suffering from hemiplegic paralysis, by which the right arm was rendered useless, though the leg still retained traces of sensation, and was in some slight measure amenable to will. For some time he had been under the care of a local conjuror who, acknowledging his inability to deal with so great a number of spirits as were here involved, had demanded assistance.

When the sufferer was first introduced to the assemblage he was submitted to a searching cross-examination as to forgotten and neglected vows. Then, after a few uneventful preliminaries, such as looking into amulets to define the number and character of the offending demons, he was placed in the midst of the conjurors, who ranged themselves in a circle to the left of the fire.

Pou-ni-ka-ma-ta—he of the antlered head—led the jig, the entire conjuring crew circling round and round the invalid in single file, chanting a refrain indicative of the unity of purpose and the power of spirits; and this was repeated over and over again until replaced by another higher in key and more emphatic in movement and enunciation, that, in turn, gave way to a third, embodying still more prominently the peculiarities of the one immediately preceding. During all this marching, which towards the last became a stamping quick-step, the performers, each and severally, as the "spirits moved," cast into the blaze

† *Medicine*, in its savage sense, admits of no change in orthography, whether employed in the singular or plural, as a noun or verb, adjective or adverb.

various animal and other substances taken from their *medicine-bags*, selected in accordance with some superstition or fancy that imbued it with *medicine*.*

Turn and turn about these chants were repeated to a constant accompaniment of drums, bells, and gourds, as manipulated by the novices seated at the opposite side of the fire, who varied the music in accordance with the cadence of the voices of their superiors, now and again instituting foul scents on their own account, or chorusing the din with responsive shrieks and howls.

For an hour, perhaps, this continued, when the conjuring crew abruptly came to a halt, facing with military precision towards the centre. At a final flourish of drums and rattles each stretched forth the right hand, with the *medicine-bag* in its grasp, pointing at the sufferer; and this position was silently and rigidly maintained for what seemed an unconscionable period of time (though really but a few seconds), when the *Elk* suddenly uttered a sharp authoritative, "*Hugh!—Begone!*" and march and tune began anew.

Three times these ceremonies were gone over in all detail, and three times the obtrusive spirits were bidden to depart. Then, in response to a query of *Pou-ni-ka-ma-ta's*, the conjured admitted some return of sensation, and that the arm "prickled as if waking from *big sleep*."

Simultaneously with the expiration of the ninth series of ceremonials, the poor fellow became ecstatic,—sprang in mid-air, whirling the maimed member about his head with great rapidity and violence (seemingly with perfect command thereof), at the same time uttering blood-curdling shrieks and yells; then fell to dancing to music of his own improvising,—far from sentimental or entrancing,—conducting himself for all the world as if possessed by an infinite number of those pork-loving gentry that appear in Scripture under the name of "*Legion*,"—as undoubtedly he was.

Not a soul offered to interfere. Indeed, all appeared to regard it as quite a matter of course. And when the poor *be-medicated* devil

sank to the ground, helpless, exhausted, frothing at the lips, and with every muscle tense and spasmodically twitching, not a hand was offered in relief. After a few moments' gazing, audience and performers quietly dispersed, while some friends lifted the unfortunate to his lodge, and there left him alone to recover or die as chance might determine. Justice compels me to add that this apparent stoicism was less due to indifference than to the fact the man was *medicine*, and hence not to be interfered with lest the spell should be undone and the wrath of the spirits be transferred to the meddlers.†

The day following I visited the patient at his own wigwam. He assured me he possessed no remembrance of anything that had transpired subsequent to the moment he announced partial restoration of sensation. Availing myself of the opportunity to examine him, to my amazement I found the two lateral halves of the body coequal in sensation and movement, though the diseased side of course retained its atrophied condition. He was confident permanent relief had been obtained, which I, of course, conceded,—barring certain mental reservations. Subsequently the paralysis returned, completely affecting the right half of the body, the leg for the first time being wholly beyond control. When I left the neighborhood a second conjuration was on the tapis, but I have no means of knowing its results. However, there were reasons convincing to any medical man why there should be no permanent change save for the *worse*.‡

On another occasion, a more than ordinarily intelligent Indian employed as interpreter at a Mission, was taken suddenly with lameness, resultant upon *sciatica*. The resident missionary, who had exhausted his own resources in the way of embrocations and patent medicines, professed positive belief in the fellow's complete conversion to the tenets of Christianity, an opinion in which, from previous knowledge of savage character, I did not at all concur. The aid sought at my hands was necessarily withheld, for reasons unnecessary to repeat, but I promised to see the man and examine him, with a view to determining the exact nature of the malady. On interrogating the latter closely and in private, I discovered he believed himself "*bewitched*," and that for some time (surrepti-

* The theory is that by disciplining spirits of the same class a threat is conveyed to those afflicting the individual or sufferer; hence the burning of bones, entrails, hair, etc., serves a double purpose,—the odors attract the attention of the offending spirits, who are thus made to witness the tortures which the spirits of the articles burned are thus forced to undergo. So salutary a warning cannot but be accepted, save in the case of the excessively evil, who *may* require to be *coaxed*. The songs for the most part are alternate promises and threats; and juggling is intended to *amuse* the spirits.

† Note the analogy to the demonology of the New Testament and early Christian era!

‡ See Samuel Hearne's account of similar procedure, Appendix I.

tiously, of course) he had been under the care of a local *Sham*, who declared the cause of suffering to be "*two worms and a stone*." By strenuous exertions the *medicine-man* had removed *one* worm from the limb, but its fellow and the pebble defied all his efforts, and three other *medicine-men* had been summoned to his aid, whose arrival was hourly expected.

Determined to witness the conjuration, I posted off to the local *Sham* (the worthy missionary had assured me there was not one in the region,—he had converted them all),* whose consent and good will were easily obtained once he understood I was pledged to secrecy.

The expected conjurors came. In the wigwam of the interpreter they gathered, with the invalid in their midst. The chief man drew from his *medicine-bag* a piece of rock-crystal, into which he gazed long and earnestly, then, passing it to the nearest of his brethren, an-

* The innocence and simplicity of this most worthy gentleman, like the majority of missionaries, wholly unfit to cope with the cunning of the savage, either mentally or physically, was quite refreshing. It brings to mind the criticism of Dr. W. H. Dall after hearing a number of Slavés render a hymn with excellent effect: "Altogether it was a scene that would have delighted the hearts of many people who know nothing of Indian character, and as such will doubtless figure in some missionary report. But to any one who at all understands the situation, the absurdity of the proceeding was so palpable that it appeared almost like blasphemy. Old Sakhniti, who has at least eighteen wives, whose hands are bloody with repeated and most atrocious murders, who knows nothing of what we understand by right and wrong, or by future state of reward and punishment,—this old heathen was singing as sweetly as his voice would allow, and with quite as much comprehension of the hymn as one of the dogs in the yard. Indians are fond of singing; they are also fond of tobacco, and for a pipeful apiece one may baptize a whole tribe. Why will intelligent men still go on talking three or four times a year to Indians on doctrinal subjects by means of a jargon which cannot express a single abstract idea, and the use of which throws ridicule on sacred things, and still call such work 'spreading the truths of Christianity'?" ("Alaska and its Resources," p. 111.)

The truth of the foregoing I can fully corroborate, and will add that it is an error to attempt definitely to convey to primitive peoples ideas of future rewards and punishments that are wholly opposed to their tastes and inclinations, and wholly unsuited to their modes of life. An Otchipwe, on being urged by a missionary to become a Christian that he might "go to heaven," replied that he had not the least desire to be one; that if he were a Christian he would prefer *Hades* to Heaven, because, in the former case, though in pain, he would be permitted to stand up and walk about, while in the latter he would be forced to sit still and sing psalms all day! And this reply was not given in jest or in mockery, but in sober earnest.

nounced he saw in the diseased limb not only the remaining worm and the pebble, but a *piece of iron, another stone, and a crooked nail*. No wonder the poor fellow was lame! With the aid of this "*powerful medicine*" the others had no difficulty in affirming the diagnosis, and accordingly it was determined to submit the sufferer to the ordeal of their united conjurations the next evening at the hour the moon would be full.†

The affair was not a success, however, owing to outside interference. It was scarce under way ere the clergyman, who somehow had got wind of the affair, burst into the assemblage and carried off the interpreter, and the following day sent him to the nearest civilized settlement for treatment; and to his great astonishment and sorrow, he discovered in the *Shams* four of his most promising converts, who, when upbraided for their duplicity, chaffed him, saying they had tried his *medicine* and found it "*ca-win-a-shin*,"—not much account.

All savages hold civilized medicine in unbounded respect, and withal, no little fear; and as physiological action or function is entirely beyond their comprehension, it is supposed our pharmaceutical products possess kindred action with their own amulets,—that they influence and secure the aid of spirits unknown to Indians: consequently they submit unquestioningly to the *dicta* of civilized physicians, providing they are not deemed inimical to their race.

An instrument or medicine-case is an object of never-ending reverence and awe, and more feared than even their own devil and Little-Men-haunted caverns; and a savage unfamiliar with civilized ways would prefer to risk a single-handed contest with a grizzly or polar bear than tempt the mysterious powers of a medicine-chest by lifting its cover. The mere display of powders and bottles, or the accidental dropping of the mystic word *medicine*, is usually sufficient to stampede an audience, who hasten to rid themselves of chance occult influences.

A laughable incident occurred at the Touchwood Hills (Manitoba) in 1858, during the presence of the Canadian commissioner, Mr. H. Youle Hinde. The half-breed wife of the local trader desired some adhesive-plaster, which Mr. Hinde undertook to supply from a

† The *fee* demanded in this instance was four bottles of *ishkodiwauboo ouiski* ("whiskey; fire-water") obtained from an illicit trader, four green blankets, four red blankets, and twenty pounds of tobacco, which was paid in advance.

box on which sat an Indian *Sham* and his novice. The woman inquired if it would be safe for her to remain in the room while the medicines were opened, and a joking negative from the husband caused her to quickly disappear. Next, the Indians, who had not understood the conversation, it being English, rose at the motion of Mr. Hinde, and watched his movements inquisitively; but no sooner was the box opened than they were taken as with a panic, rushed from the house, and hastening to the summit of a neighboring hill, there divested themselves of all clothing, and for hours sat squatting in the sun to await the deodorizing influences of breeze and solar rays.

Those, too, who have witnessed the repose and insensibility to pain brought about by narcotics and anæsthetics, hold such in idolatrous reverence, especially the latter. A physician of my acquaintance administered chloroform to perform an amputation upon a Dacotah brave, and the fame of the "*great medicine*" spread from the Mississippi to the Yellowstone, and thereafter he was constantly pestered by those who desired to possess a portion of the fluid. One young chief who had been particularly unfortunate in war and hunting expeditions, offered in exchange for the smallest quantity his horse and trappings, arms, twenty bison-skins, a new *tepté*, and, last but not least, his *squaw*! He was gotten rid of by an assurance the *medicine* would not stay with him, a few drops being given in a loosely-corked phial, which bore out the statement. The anxiety to possess the drug was with no desire of administering it, but under the supposition the spirit controlling so powerful a charm could not but lend favorable influence to the conjurations of its possessor.

It is generally supposed Indian tribes are comparatively free from disease, and this is frequently affirmed by intelligent men, who, oddly enough, appear to suppose that an absence of everything which civilization deems essential to existence—comfortable shelter, clothing, proper and sufficient food, etc.—must insure the savage man immunity from illness and death. No greater error can be imagined. Few of the human race, of any nation, clime, or condition of life, ever die from *old age*; and as my friend Dr. Winder, formerly physician to the *Wekimikong* Reserve (Great Manatoulin Island), was wont to remark, "A dead Indian in the wilds is by no means so great a rarity as a dead ass in the midst of European civilization!"

APPENDIX.

E.

A Romish priest, formerly a professor in the University of Louvain, a simple, honest, guileless man, whose acquaintance with Indian life and character extended over more than twenty years of missionary service in the wildest part of upper British Columbia and the west slope of the Rocky Mountains,—a man whose devotion and purity was such as to challenge the admiration of all, Catholic, Protestant, and pagan, white or savage, alike, and whose generous catholicity of spirit and graces of mind made him a companion at once charming and instructive,—during a discussion of savage psychomancy, remarked, "I have seen many exhibitions of power which my philosophy cannot explain, and have seen *medicine* tested in most conclusive ways. I once saw a Kootenai Indian, known as *Shookum-tama-herewos*, command a mountain sheep to fall dead, and the *creature then leaping among the rocks of the mountain-side fell instantly lifeless*. This I saw with my own eyes, and I ate of the animal afterwards. It was unwounded, healthy, and perfectly wild! Ah!" (and he shuddered as he spoke) "they seem to have power from Sathanus!"

F.

On one occasion a party of ten *voyageurs* set out from Fort Benton for the purpose of finding the Kaime or Blood-Band of Blackfeet, their route lying due north, crossing the boundary-line near *Nee-na-sa-ko* ("Chief Mountain") and *O-max-ten* ("Great Lake"), and extending indefinitely beyond the Saskatchewan and towards the tributaries of the Mackenzie and Coppermine Rivers. The expedition was perilous, and the danger became more imminent with each day's journey, war-trails, war-party fires, and similar indications of hostile bands constantly appearing in increased numbers. The adventurers soon found they were in the midst of the Cree war-party's operations (the Crees, friendly to the Hudson's Bay Company, were inimicable to American fur traders), and so full of danger was every day's travel that seven of the ten turned back. The others continued the journey until finally their resolution failed, and they determined to return after another day's travel to the northward. On the afternoon of the last day four Indians were seen who, after a cautious approach, made the sign of peace, laid down their arms, and came forward, announcing themselves as *Kaimes*. They were sent out, they said, by *Ma-gue-a-poos* (the "Wolf's Word") to find three whites, mounted on horses of a peculiar color, dressed in garments accurately delineated, and armed with weapons that they without seeing accurately described. The whole history of the expedition had been given to them by *Ma-gue-a-poos*. The purpose of the journey, the *personnel* of the party, the exact locality where to find the three who persevered, had been detailed by him with as much fidelity as could have been done by one of the whites themselves, and so convinced were the tribe of the truth of the seer's *medicine* that they sent these four young men to meet the whites and conduct them safely to a rendezvous more than a hundred miles away. On arrival the whites found the whole camp of "Rising Head," a noted war chief, awaiting them. The objects of the expedition were accomplished, and, after a few days, the traders returned to safer haunts. "I was at the head of this party of whites, and personally met the messengers," says J. Mason Browne, of the American Fur Company, "and upon

questioning the chief men of the Indian camp, many of whom afterwards became my warm personal friends, no suspicion could be had of the accuracy of the facts as related. Subsequent intimate acquaintance with *Ma-que-a-poo*s disclosed a *medicine* faculty as accurate as it was inexplicable, yet he never claimed the gift entitled him to any particular regard, except as an instrument of a power he did not pretend to understand." Of the facts as above related "he could give no explanation beyond the general one that he saw us coming and heard us talk on our journey, and he had not, during that time, been absent from the Indian camp." (*Atlantic Monthly*, July, 1866.)

The phenomena of "second sight" extensively obtains among the Blackfeet, Crees, Chepewyans, and Slavés. An aged uncle (by the mother's side) of the McKay boys, Scotch half-breeds well known in the earlier days of Manitoba, was famous for his powers, though not a *Sham*, and with no pretensions to *medicine*. His power was derived suddenly, remained a few years, and as unexpectedly disappeared. He neither dreamed, professed to see visions, nor to enter upon trance, but sat wrapped in apparent meditation, with partially-closed eyes, and repeated what he saw. He constantly directed hunters to where bison and other game could be found, never making an error in description or in fact. A man had the lock of his gun blown away while firing at a bison cow. Assisted by friends he searched everywhere in vain. The next morning the seer said to him, "The lock is ten yards away from where the cow fell, close to a badger-heap, and you will see it glisten in the sun as soon as you get near." And so it proved. Again, some horses that had been given up as irrecoverable, were found by his direction in an out-of-the-way place near Scratching River.

G.

One conjuror I knew intimately would allow himself to be bound hand and foot with rawhide thongs, the whole body enveloped in such a way as to pinion arms and hands to his sides, yet the instant a blanket was cast over him he would bound to his feet free, the bonds in his hands with the fastenings intact. Once I bound his naked form with powerful strips of green moose-hide, drawing them so tightly blood threatened to burst from the ridges of unimprisoned flesh, but it made not the least difference so far as I could discover. On another occasion, in the middle of the day, he was even more elaborately pinioned, wound and rewound, until he appeared an improvised mummy, employing knots and turns suggested by naval experience; and he passed from my hands into a small "*medicine* lodge," devoid of all furnishings save rattle and drum, erected in the midst of open prairie. Scarcely was he concealed from view when both instruments began a low accompaniment to a chant he sang, and the air all about became vocal with a multitude of noises and sounds, some high overhead, some apparently far away, and others in the grass at our feet. Bison bellowed, bears growled, wapiti stags roared, wolves howled, frogs croaked, horses neighed and galloped, dogs and foxes barked, serpents rattled and hissed, squirrels and hares rustled and squeaked, the cat tribes spat and swore, and even wild fowl flapped their wings and uttered their woted cries; not separately, but all in one chorus, constituting a feat of ventriloquism, if such it was, unparalleled. When the sounds subsided, *Wa-ah-poo*s ("The Rabbit") appeared at the entrance of the tent, while the bonds, for which diligent search was

made, were missing. Calling to him an Iroquois, an utter stranger to all but myself, and who had but the day before arrived from beyond the Great Lakes in Ontario, he directed him to a certain tree on a bluff a mile away, bidding him bring what would there be found suspended from a designated branch. The latter returned with what appeared to be the bonds intact, and had I not been assured of the impossibility of transporting them to that distance I would have had no hesitancy in believing they were those with which the conjuror had been bound, so exactly did every turn and knot appear to be my very own. A few days later the same wizard, while conjuring a squaw in the final stage of phthisis, suddenly thrust his hands beneath the blanket that enveloped her emaciated form, and dragged forth the carcass of a full-grown wolf, which he flung outside into the midst of assembled relatives and friends, by whom it was quickly pounded and trampled into an unrecognizable pulp. "The Rabbit" now announced the woman would recover; but, on the contrary, she died the same night, a result of which I had warned him, but only to obtain the response it "mattered little." He found a ready excuse in *another spirit*, a near relative of the first, who had unexpectedly returned from a long journey, and taken advantage of his (*Wa-ah-poo*s's) temporary absence to work its evil purpose. Where he obtained the wolf is beyond my conjecture. There was nothing of the kind beneath the blanket five minutes before it was brought to light, for I had just given the sufferer careful examination. There was but one other person within the lodge, the husband, collusion with whom was manifestly impossible. No person had passed in or out for above an hour, and the costume of the conjuror, merely a breech-clout and *medicine-bag*, offered no means of concealment. (*Popular Science Monthly*, September, 1886.)

H.

The "Black-Snake," a distinguished ornament of the tribe of Mountain Assiniboines (the only tribe save the Cherokees that possesses a written language), dwelt alone on a far northern branch of the Saskatchewan, revered for his gifts, feared for his power, and always approached with reluctance because of his austerity and taciturnity; moreover, he was difficult of access, and as vain and ambitious as he was haughty and contemptuous. Mr. Browne relates a trial of *medicine* that took place between him and a renowned *Sham* of a neighboring tribe in 1855, which I have subsequently heard verified by eye-witnesses whose veracity is unimpeachable. The rivals, in full paraphernalia, war-paint, and decorations, met in the midst of a concourse of more than two thousand people,—whites, Indians, and half-breeds. Both had prepared for the ordeal by long fasting and conjuration. After the pipe, which precedes all important councils, the *Shams* sat down opposite each other, a few feet apart. For some four hours they glared fiercely in each other's eyes, when the "Black Snake," observing his rival trembling and swaying from side to side, sprang to his feet, and pointing at him a black pebble worn suspended from the neck in lieu of a *medicine-bag*, stamped his foot and commanded he should "*Die*." The unfortunate for a few seconds swayed more violently, then fell over upon his side, lifeless! This purely psychical result gave the "Black Snake" a pre-eminence that extended throughout all the Northwest, even into the camps of his hereditary enemies; his word sufficed to prevent or procure war, and a message to his foes would at any moment

cause them to turn from the war-path. Poison, deception, or collusion, in this instance, are useless suggestions.

I.

"One man was so dangerously ill that it was thought necessary the conjurors should use some of those wonderful experiments for his recovery; one of them therefore consented to swallow a broad bayonet. . . . After a long preparatory discourse and the necessary conference with his familiar spirit, or 'shadows' as they call them, he advanced to the door and called for the bayonet, which was then ready prepared by having a string fastened to it, and a short piece of wood tied to the other end of the string to prevent him swallowing it. I could not help observing that the length of the piece of wood was not more than the breadth of the bayonet; however, as it answered the intended purpose, it did equally as well as if it had been a long hand-spike.

"Though I am not so credulous as to believe that the conjuror absolutely swallowed the bayonet, yet I must acknowledge that in the twinkling of an eye he conveyed it,—God knows where! and the small piece of wood, or one exactly like it, was confined close to his teeth. He then paraded backward and forward before the conjuring-house for a short time, when he feigned to be greatly disordered in his stomach and bowels, and after making many wry faces, and groaning most hideously, he put his body into several distorted attitudes very suitable to the occasion. He then returned to the door of the conjuring-house, and after making many strong efforts to vomit, by the help of the string he at length, and after tugging at it some time, produced the bayonet, which, apparently, he hauled out of his mouth, to the no small surprise of those present. He then looked around with an air of exultation, and strutting into the conjuring-house, renewed his incantations, and continued them without intermission for twenty-four hours. Though I was not close to his elbow when he performed the above feat, yet I thought myself (and I can assure my readers I was all attention) to have detected him. Indeed, I must confess it was a very nice piece of deception, especially as it was performed by a man quite naked. . . . The sick man, however, soon recovered." (Pp. 193, 194.) . . . "During our stay at Anaw'd Lake, as several of the Indians were sickly, the doctors undertook to administer relief; particularly to one man, who had been hauled on a sledge by his brother for two months. His disorder was the *dead palsy*, which affected one side from the crown of his head to the sole of his foot. Besides this dreadful disorder, he had some inward complaints, with a total loss of appetite, so that he was reduced to a mere skeleton, and so weak as to be scarcely capable of speaking. In this deplorable condition, he was laid in the centre of a large conjuring-house, and that nothing might be wanting towards his recovery, the same man who deceived me by swallowing a bayonet . . . now offered to swallow a large piece of board about the size of a barrel stave. . . . When he put it to his mouth it apparently slipped down his throat like lightning, and only left about three inches sticking without his lips; after walking backward and forward three times, he hauled it up again, and ran into the conjuring-house with great precipitation. This he did, to all appearance, with great ease and composure; and notwithstanding I was all attention on the occasion, I could not detect the deceit; and as to the reality of it being a piece of wood . . . I had it in my hand both before and immediately after the cere-

mony. . . . On the day preceding . . . I accidentally came across the conjuror . . . several miles from the tents . . . busily employed in shaping a piece of wood exactly like that part which stuck out of his mouth after he had pretended to swallow the remainder of the piece. The shape of the piece which I saw him making was this , which exactly resembled the forked end of the main piece, the shape of which was this, , so that when the attendants concealed the main piece, it was easy for him to stick the small point into his mouth. . . . My guide Matonabee, with all his other good sense, was so bigoted to the reality of those performances that he assured me in the strongest terms he had seen a man, who was then in company, swallow a child's cradle with as much ease as he could fold up a piece of paper and put it in his mouth; and that when he hauled it up again, not the mark of a tooth or any violence was to be discovered about it. . . . As soon as our conjuror had executed the above feat, and entered the conjuring-house as already mentioned, five other men and an old woman, all of whom were great professors of the art, stripped themselves quite naked and followed him, when they soon began to blow, suck, sing, and dance around the poor paralytic, and continued to do so for three days and four nights. . . . And it is truly wonderful, though the strictest truth, that when the poor sick man was taken from the conjuring-house he had not only recovered his appetite to an amazing degree, but was able to move all the fingers and toes of the side that had so long been dead. In three weeks he had recovered so far as to be capable of walking, and at the end of six weeks went a hunting for his family. . . . He accompanied me back to Prince of Wales Fort in 1772, and since that time has frequently visited the factory." (*Hearne's Journey*, pp. 213 to 220.)

RECTAL ALIMENTATION BY SUPPOSITORIES.

BY SAMUEL WESLEY GADD, M.D., PHILADELPHIA, PA.

RECTAL ALIMENTATION is frequently resorted to when the stomach is unable to bear food or digest it by reason of the various diseases to which the stomach is susceptible.

Before proceeding to speak of the application of rectal alimentation in the form of suppositories, it might be well for us briefly to consider the anatomy of the rectum, which is the place of immediate lodgment of the suppositories intended for alimentation.

This we find to be a continuation of the bowel, being really a part of it, lined with a mucous membrane containing a few solitary glands, surrounded by numerous blood-vessels which anastomose freely, causing it to be very vascular, and consequently very absorbent. Lymphatic vessels are also found here of large size. The sphincter ani also acts the part of a pylorus to this part, enabling it to

retain that which may be placed within it for a considerable length of time.

From these facts we deduce that the rectum is well constituted for absorbing substances, especially such substances as are diffusible or dialyzable. Not that the substances enter into the body exactly by means of dialysis, but that those substances which are dialyzable are more readily taken up by the blood than those which are not. Whilst the lower bowel—of which the rectum is a part—cannot perform the function of the stomach, namely, that of digestion, it can and does very well perform the functions of the small bowel, namely, assimilation or absorption, when called upon to do so.

Hence, if we administer to the lower bowel such foods as have been already digested, it can very readily appropriate the same to the blood.

Of course the amount of nourishment taken into the system is relatively small, but every physician knows what a small quantity at times, when the patient's life hangs as it were over the brink of the grave by a slender thread, is sufficient to tide him over the moment of wrestling for life, until his own strength begins to return and the normal functions again show their presence.

Recognizing, then, these facts, nutritive enemata are frequently resorted to in diseases of the stomach, or in such cases where the stomach or upper bowel demands rest, with very beneficial results, if not to the recovery of patients, at least to a considerable prolongation of life.

The use of nutrient suppositories has been suggested, but I believe they have not yet been brought to practical use. The consideration of this caused me to carry on some experiments with a view to the best manner of producing them.

Digestion really is the conversion of the articles we eat as food,—the most of which being as yet crude and incapable of being taken up by the blood,—by means of the gastric or pancreatic fluids, into such substances as shall be readily taken up by the blood, and by it readily appropriated to the demands of the system. Thus starch is changed into glucose, proteids into peptones. The pancreatic fluid is the most active in this change, and therefore the most important.

If, now, we act upon proteid matter with an artificial pancreatic fluid, which can be readily obtained from a fresh pancreas, under the same conditions by which digestion is effected in the stomach or duodenum, namely,

a temperature of about 100° F., and an alkaline medium in connection with pancreatic fluid, or an acid medium if the gastric fluid is engaged, we produce an artificial digestion, which is precisely identical, as far as it goes, with that performed by the stomach or pancreas in the duodenum.

For this purpose I proceeded to prepare a pancreatized extract of beef in the following manner :

I made use of liquor pancreaticus as representing pancreatine, made according to the method recommended by Mr. Bengier, of London, namely, by digesting the fresh pancreas in four times its weight of diluted alcohol. Of course the extract of pancreatine may be used with the same results, but I desire in this paper to speak of that method which is most easily performed by the ordinary pharmacist, so that he may be able to prepare the whole from beginning to ending.

After numerous experiments, I have decided upon the following as being the best method and the best proportions for making the extract of meat :

To sixteen ounces avoirdupois of finely-minced beef, off the rump, add one pint of water and two fluidounces of liquor pancreaticus and one drachm of sodium carbonate.

The mixture should be kept at a temperature of about 120° to 140° F., with occasional stirring from four to six hours, adding water from time to time as it becomes lost by evaporation. Then throw the whole upon a linen or muslin strainer, and express with gentle pressure. Neutralize the filtrate with hydrochloric acid in a porcelain dish, and, with a moderate degree of heat, evaporate down to the consistence of an extract, or, better, to dryness, if it can be accomplished without a high degree of heat. A much better preparation I think could be obtained by evaporating *in vacuo*. This extract of meat will keep well in a closed vessel, and represents thoroughly, if made with care, the nutritive value of the meat.

By operating in this manner upon different samples of beef, I found that the resulting extract varied from two hundred and ninety grains to four hundred and fifty grains to the pound of beef used. This average weight excludes the amount of sodium chloride present formed by neutralizing the sodium carbonate with hydrochloric acid.

Various substances have been used as a base for suppositories, such as tallow, starch and glycerin, cacao butter, glycerin and gelatin, etc. The cacao butter is that which is

most frequently used in this country, chiefly because of its cheapness and the ease it admits of manipulation. But in my hands, after various experiments, the superiority rests with the mixture of gelatin and glycerin, which, for convenience, we will call *glycogelatin*.

Glycogelatin is made by taking one ounce avoirdupois of pure gelatin; cause it to become soft by soaking in one fluidounce of water until the whole of the water has become absorbed. Dissolve this in three and a half fluidounces of glycerin by means of a water-bath, and allow the mass to cool and solidify.

When ordering suppositories this can be prescribed for, just as cacao butter is, and should be manipulated in precisely the same manner. They are, I confess, a little more tedious to prepare than those made with cacao butter, but the superiority of the glycogelatin suppositories is sufficient to warrant the physician in demanding this kind, although it may require an extra amount of labor on the part of the pharmacist in their preparation.

If cacao butter suppositories that have been made for some time be examined they will be seen to be coated with a powder of a whitish color, which is the result of the oxidation or rancidifying of the cacao butter, and if introduced into the rectum may produce a certain amount of irritation. Whereas I have before me now glycogelatin suppositories of morphine, and of quinine and opium, which I made several months ago, and which appear to-day as sweet as when first turned out of the mould.

If the suppositories are made up as they are written for, this objection would be obviated; but in medicine it is always well to provide against all possibilities which might prove detrimental to the object sought for by the medicines employed.

Now, to make the pancreatized extract of meat into suppositories, first rub up the extract with a few drops of water in a mortar which has been previously warmed until it becomes uniformly smooth. Next add the glycogelatin or cacao butter in a fused condition; stir the whole until it is about to congeal; then pour into moulds of a suitable size.

These may be from the "baby" size, weighing fifteen grains, to the larger size of forty-five grains each.

When using cacao butter I found that by incorporating a small amount of wax with the cacao butter—and for this purpose the yellow is better than the white—a larger amount of the extract of meat can be used without materially affecting the melting of the suppository at the temperature of the rectum.

The dried extract of meat will keep perfectly sweet for a long time in a closed vessel.

When nutrient suppositories are desired they may be prescribed for thus:

R Extracti carnis pancreatici, gr. c;
Olei theobromæ, vel
Glycogelatinæ, q.s.
Ft. suppositor. x.

By ordering in this form the amount of ol. theobromæ or of glycogelatin can be regulated by the pharmacist to the size of his suppository mould, and the physician, by ordering a definite quantity of extract of meat, made up into a definite number of suppositories, will be cognizant of the strength of each, and can determine how many should be used in a given time.

As I have before stated, if the suppositories are used while they are fresh it makes little difference whether cacao butter or glycogelatin be used.

There is an important point to be observed in the use of suppositories of any kind, namely, that of oiling them before introducing them. This is more essential with those made with glycogelatin than those made with cacao butter. With the latter, however, it may scarcely be necessary to do so in warm weather; but if in winter, or if extra hard, or if covered with a dusting powder, which is often done unthinkingly by the pharmacist, or if the anus be inflamed, fissured, etc., as is often the case, the introduction of a suppository not previously oiled will give some discomfort.

This I know is not generally considered by physicians, but as I have learned it by experimental experience I deem it of sufficient importance to be mentioned in this paper.

Such a method of performing rectal alimentation would bring the manufacture of such within the domain of pharmacists rather than that of domestic preparation, and to some minds may appear to be too expensive, yet the cost would not be so much if prescribed for in quantity.

The advantages of this form of alimentation are self-evident. The suppositories will keep any reasonable length of time, which cannot be said of the liquid injections. Less care is required in their introduction than when a syringe is used, and this in the hands of a careless nurse may do harm to the rectum of the patient.

Greater ease of introduction, as well as less exposure, are also points of not small importance.

SOME POINTS IN THE PATHOLOGY AND TREATMENT OF FEVER.

At a meeting of the Manchester Medical Society, held March 2, 1887, DR. JAMES NIVEN read a paper on the above subject. The points considered were formulated in four propositions:

1. Self-protective fevers tend to become milder the longer they are settled in a community. The protection conferred was regarded as an adjustment of the tissues, which would be handed down from generation to generation in the case of any disease which was spread over the greater part of a community. In co operation with this adjustment is the elimination by death of people specially liable to the disease. In opposition to it is the tendency of children to take disease in the same manner as the parent. As illustrations were considered typhoid fever, measles, small-pox, yellow fever, and syphilis.

2. The second proposition was that the phenomena of fever are probably due in the main to chemical poisons. It was attempted to be shown that chemical matters secreted by the fungi or dead fungi were sufficient to account for the phenomena of fevers, while in some diseases it was taken as proved that only chemical poisons were admitted into the circulation.

3. The third proposition was that the nervous system is the liberator and controller of heat in fever. It was contended that a large amount of heat was due to metabolism of muscle, but the experiments of Pflüger and Samuel had shown that muscle, under normal circumstances, underwent this metabolism as the effect of nervous impulses. While admitting the vaso-motor system and heat-inhibitory centres as probable causes of some pyrexial conditions, it was suggested that excitation of the anterior cornual cells in the spinal cord, and of their congeners in the medulla and brain, would better explain the pyrexial conditions of such fevers as typhoid and typhus. Reasons were given for regarding the figures arrived at by Dr. Burdon Sanderson, from calculation of the excreta in health and in fever, as showing an increase in fever of heat requiring to be eliminated.

4. The fourth proposition was that the proper treatment of fevers is partly dietetic, partly calmative. The treatment on these lines was sketched. Easily assimilable materials, such as peptonized meat and milk, and sugared fruit, are necessary to maintain the strength, and to prevent complications and

tropho-neuroses; perforation in typhoid may be regarded as in part a tropho-neurosis. Calmative treatment, such as a skilful nurse, free from fuss, removal of irritations, and antipyretic treatment, are necessary for the same objects. Antifebrin was regarded as, perhaps, the best antipyretic.—*British Medical Journal*, March 19, 1887.

TREATMENT OF HEMORRHAGE FROM THE TONGUE.

At a meeting of the Medical Society of London, held Monday, April 18, 1887, MR. LOCKWOOD (*Lancet*, April 23, 1887) read a paper on a "Mode of restraining Hemorrhage during Operations upon the Tongue." After speaking of the serious nature of that accident, the various plans which had been devised to prevent it were mentioned. None of these seemed to be quite free from objection, although all were more or less efficacious. After discussing the anatomy of the lingual artery, it was concluded that, at the place where the vessel lay upon the side of the pharynx near the greater cornu of the hyoid bone, the depth of tissues was so small that there could be no difficulty in compressing the vessel. The great constancy of the course of the vessel lent itself to this proposal. Forceps were then described which had been devised after a great many experiments upon the dead body. These instruments were quite efficient in preventing the passage of thin injection through the lingual artery. They were so arranged that one blade passed by the side of the tongue into the pharynx, while the other was bent to fit the contour of the lower jaw, and met the other near the tip of the greater cornu of the hyoid bone. Dissections had been made after the forceps had been adjusted, which showed that the artery was tightly grasped and impermeable. A case was then described in which Mr. Lockwood had removed half the tongue while the forceps were in position. The tongue was split down the median septum and then removed with scissors. The lingual artery did not pulsate or bleed, and the operation was rapid and bloodless. Other cases were then described in which Mr. Willett had used the forceps; and, in conclusion, it was thought that there was a sufficient amount of evidence to show that the lingual artery might be easily and safely compressed.

Leading Articles.

SULPHURETTED HYDROGEN.

IN the last issue of the THERAPEUTIC GAZETTE Dr. H. C. Wood published an article upon the use of sulphuretted hydrogen in phthisis, giving a *résumé* of the results which so far have been reached in the use of the remedy, and contending that its effects upon the general system were the same when given by the mouth as when injected into the bowels.

That the sulphuretted hydrogen given by the mouth has the same general effect as when given by the bowels seems to us self-evident; in each case the remedy must enter the portal vein and through it be distributed to the general circulation. Dr. Wood's clinical experience confirms this, excepting in so far as it indicates that the absorption from the stomach is more certain and definite than from the bowels. A pronounced odor upon the breath of patients who have taken the gaseous enema is not common, but within a few minutes after taking a full dose of the sulphuretted hydrogen water the fetor of the breath is usually very disagreeable. The dose of the saturated solution is one ounce, taken from

three to five times a day; preferably in carbonic-acid water, as suggested by Dr. Wood.

The remedy seems to be very important in the treatment of pulmonic catarrhal inflammations, but there is still no strong evidence that it has any specific action in phthisis. We have known cases of severe chronic cystitis rapidly cured by the use of natural sulphur waters, and it is probable that the artificial sulphuretted hydrogen water will be found efficacious in catarrh of the bladder. It also ought to be tried in chronic intestinal catarrhs.

Artificial sulphuretted hydrogen solution has a very pronounced tendency to undergo decomposition with the deposition of sulphur. It is possible that chloride of sodium or other mineral salts added to the water would tend to prevent this, since the natural waters long retain their sulphur. Experiments are, however, necessary to decide the truth of this surmise.

A little carelessness in the preparation of sulphuretted hydrogen water also causes it to be very weak in the gas, so that a much more uniform and active preparation can be obtained by the patient making it carefully at home than by purchasing it of a careless apothecary. For this purpose, at the suggestion of Dr. Wood, an apparatus has been devised and prepared by Dr. Marshall, of the chemical laboratory of the University of Pennsylvania. The apparatus should be kept in a cellar or other cool place, and at least every other day the necessary amount of the sulphuretted hydrogen water should be made.

With the apparatus are furnished the necessary chemicals and the printed directions for use. Moreover, Dr. Marshall has so calculated and arranged the mixtures that the water is simultaneously impregnated with carbonic acid and sulphuretted hydrogen. The liquid obtained has a sweetish not at all unpleasant taste.*

METHYLAL.

IN our April issue, page 269, we referred to the experiments made by Dr. B. W. Richardson as to the employment of methylal as a hypnotic. Since the appearance of this paper several articles on the subject have come under our attention, which extend our knowledge as to the action of this substance and enable us

* The price of the apparatus, boxed for shipment, is five dollars. It will be furnished on application by letter, by Dr. Marshall. Address Chemical Laboratory University of Pennsylvania, Philadelphia.

to determine its position with greater accuracy. Methylal or dimethylether was discovered in 1839 by Malaguti, and it belongs to the group of acitals. Its formula is $C_2H_5O_2$. It is soluble in water, alcohol, ethereal and fixed oils, is colorless, with a slightly acid reaction, and has an odor similar to that of chloroform and acetic ether.

Mairel and Combemale have reported in a recent meeting of the French Academy of Sciences the result of their experiments as to the physiological action of this drug. In a dose varying from $3\frac{1}{2}$ to $7\frac{1}{2}$ grains to each two pounds of body weight, these authors noted that it produced a slight degree of salivation and almost invariably quiet sleep within an hour after the injection (and they make note that hypodermic injections also appear to cause pain, and, if frequently repeated, ulcerations), lasting for six hours or more. When the dose is doubled, sleep, according to them, becomes profound. The pupil becomes dilated, the pulse increased in frequency, the salivation extremely marked, while it is almost impossible to arouse animals. These phenomena disappear after a few hours, and the sleep then appears to be natural, and a slight fall of temperature may be noted. If the dose is increased to 2 grammes for each kilogramme of body weight two distinct phases of the resulting symptoms may be recognized. In the first appear somnolence and paralytic phenomena, especially marked in the posterior extremities, and gradually becoming general, muscular insensibility, and then spontaneous convulsions, followed by diminution in general sensibility, fall of temperature, and increase in the frequency of the pulse and slight dyspnœa. Two or three hours after the commencement of the experiments the second stage appears. At this period most of the above-described morbid phenomena have disappeared, and now profound sleep is the sole remaining symptom. This, after a number of hours, passes off, and the animal recovers, but remains in a state of profound depression for several days. With still larger doses the gravity of the symptoms is increased, and death may follow, when a post-mortem examination will reveal general congestion of the brain and spinal marrow, local hemorrhages in the pulmonary tissue and renal congestion.

If given by the stomach, the same symptoms are produced by the same doses, but after a longer interval. Administered by inhalation, the authors likewise appear to have succeeded in producing unconsciousness, and

accompanied by great irritation of the ocular, nasal, and bronchial mucous membrane.

Personalì, according to the Paris correspondent of the *British Medical Journal*, April 16, 1887, likewise succeeded in producing sleep in frogs after a dose equal to fifty per cent. of their own weight; in rabbits, only twenty-five per cent.; in birds, twenty per cent.; and in dogs, ten to fifteen per cent. only was required. This author likewise found that methylal, while being rapidly eliminated, increased the action of the heart, while reducing the blood-pressure and also the temperature. These results would appear to prove that whatever be the mode of administration the general effects produced by methylal are about the same, although sleep is produced more rapidly when administered hypodermically or by inhalation than when given by the stomach. Their experiments do not, however, seem to have clearly established the fact that the somnolence produced by methylal is accompanied by sufficient anæsthesia to permit of its employment in surgical operations, and we would recall here that Dr. Richardson failed entirely in anæsthetizing animals with this substance.

Again, it is desirable to determine whether methylal is of value as a hypnotic where it is desirable to remove pain. The experiments of Mairel and Combemale would seem to indicate that this is a fact, and they believe that they are warranted in recommending it on account of the rapidity of its elimination by the lungs, and on the absence of disagreeable symptoms when its effects pass off, added to the fact that it is not accumulative in its action and is of slight toxicity.

Further experiments are desirable to determine the exact position which this drug should occupy. At present it seems best to keep it among the anodyne antispasmodics where Dr. Richardson placed it.

Personalì claims that methylal may be of value as an antidote for strychnine, and he states that if administered to a warm-blooded animal at the beginning of a strychnine-poisoning the convulsions are checked, and the poison being eliminated, the animal may recover. In the case of a cold-blooded animal, where the elimination is accomplished much more slowly, the toxic phenomena are suspended while the action of the methylal lasts, and may reappear when it has ceased.

In our April number we gave a number of modes of administration of this drug. The indications of its employment, as far as yet determined, are those which would call for

any anodyne antispasmodic, and it therefore may be employed in angina pectoris, colic, tetanus, etc. It may be given mixed with syrup in doses of about 1 fluidrachm. It has been recommended as an application for toothache, or as a liniment, in which eighty-five parts of the excipient is prepared with fifteen of methylal.

CARICA PAPAYA AS A GALACTAGOGUE.

TO us at least the employment of carica papaya as a stimulant to the mammary secretion is a novelty. We are familiar with its employment as a digestive ferment, and in a recent number have alluded to the insufficiency of the experimental data on which this employment rests. Recently the Royal Society of New South Wales appointed a committee for inquiring into the properties of this drug, and they have published a short analysis of their report in the *Australasian Medical Gazette* for February, 1887. Their experiments were made with the liquid extract containing not more than four per cent. of alcohol, a tincture of the ordinary Pharmacopœia strength, and a solid extract of a gelatinous consistency. Their experiments appear to show that the mammary secretion could be stimulated, in cases where the flow had commenced to fail, either by the internal administration of the drug or by topical applications. It is even claimed that in the virgin breast it can call forth a limpid secretion, but that this effect is merely transitory.

The committee appear to claim without reserve the greatest efficiency for carica papaya as a galactagogue. They have also noticed that when administered to pregnant patients it acts as an abortifacient.

The committee have likewise made a few experiments as regards its digestive power on meat, and while admitting that they were not considered satisfactory, the opinion was expressed that such power as was generally attributed to the drug in this particular was exerted on the sarcolemma, the muscle-cell or contents of the sarcous particles becoming released and exposed to the thorough action of the gastric juices. It was found to have no solvent action on albumen, a statement which in our opinion strongly supports our scepticism in its digestive properties.

Carica papaya, however, like many other examples that could be named, is perhaps only an example of the difference in efficiency of different preparations of the same article. We do not feel prepared to deny the presence

in carica of a ferment which under certain conditions may accomplish the solution of proteids. The only point that we would make is that the conditions under which it should be prepared and under which its activity is exerted are not yet recognized with sufficient certainty to warrant any indications for its employment.

THE NON-IDENTITY OF CAFFEINE AND THEINE.

THE non-identity of caffeine and theine, first pointed out we believe by Dr. Mays in the columns of the *GAZETTE*, has been substantiated by a paper recently read before the Royal Society, quoted by the *British Medical Journal*, April 9, 1887, by Drs. Lauder Brunton and Cash. These authors have found that theine produced a peculiar rhythmical contraction in voluntary muscles lasting for many hours. Both theine and caffeine tend to cause contraction of the muscles somewhat resembling rigor mortis. In one case the authors found that theine produced elongation of the muscle, with rhythmical movements. This phenomenon is very hard to explain on the supposition that muscular fibre contracts only in a longitudinal direction; and they suggest that possibly there might be a transverse contraction as well, which would cause elongation of the whole muscle.

THE TREATMENT OF DIPHTHERIA.

NO disease is more dreaded in the family circle and by the practitioner than diphtheria, and probably there are few affections whose therapeutics are more diverse. Diversity of treatment is the seal of unsatisfactory results, for when any treatment is assured in its effects its employment becomes universal: witness quinine *versus* malarial fevers. During the past we have ourselves settled upon a uniform method of treatment of diphtheria with results which certainly lead us to cleave fast to it, and to abandon the older plan of relying upon the combination of tincture of the chloride of iron and chlorate of potassium, a mixture whose usefulness is very doubtful. The primary and probably the most important part of the treatment is the free use of local remedies, of which Monsel's solution is, according to our thinking, the most efficacious. It should be painted very freely over the affected parts every four hours,

either undiluted or diluted with an equal bulk of glycerin. It is essential to exercise a certain amount of care and not have the brush so wet that the solution will trickle into the larynx, unless, indeed, this organ has been invaded by the disease. Next to the local treatment comes the administration of mercurials. We have so frequently seen an apparently severe attack of diphtheria abruptly aborted in its inception under the influence of large doses of calomel that we can scarcely believe that the drug has no pronounced effect. A grain of it should be put dry in the mouth of the child every hour or two until frequent very loose liquid evacuations are produced. In diphtheritic, as in other forms of angina, tincture of belladonna has seemed to us to also exert an almost specific effect. In the treatment of severe ordinary sore throat our routine plan is the free local application of the solution of subsulphate of iron, diluted or undiluted according to the exigencies of the case, the administration of mercurials in the manner just described, and the use of belladonna, 5 drops of the tincture every two to four hours according to the age of the patient. The results which we have obtained in simple sore throat indicate that in diphtheria the treatment acts not by any specific influence upon the disease-germ, but by curing a local sore throat, which is the initial lesion of diphtheria, and causes through a septic poisoning the constitutional disturbance. As a specific antiseptic medication we have used the oil of eucalyptus with apparent advantage. It should be placed in small shallow vessels near to the patient, and a sufficient heat be steadily maintained to keep the liquid boiling. In this way large quantities of the eucalyptus oil can be volatilized and the respiratory passages be perpetually bathed with the antiseptic.

In 1882, Dr. Delthil reported to one of the medical societies of Paris very pronounced results as obtained in the treatment of diphtheria by the use of inhalations of turpentine. Dr. Delthil burned continually in the sick-room a mixture of 1 kilogramme (two pounds) of coal-tar, 8 tablespoonfuls of oil of turpentine, 8 grammes (two drachms) of resin of benzoin, and 100 grammes (three and a half ounces) of cajeput oil; or a mixture of 200 grammes (seven ounces) of coal-tar, and 80 grammes (two ounces and six drachms) of oil of turpentine. It is asserted that the vapors will not cause coughing, and are generally well borne both by the patient and his attendants, and that they will dissolve the exudations and arrest the diphtheritic process in its

progress, and will assist the effects and materially secure the success of tracheotomy, if such procedure becomes necessary.

Dr. Schenker has recently been experimenting upon thirty-six cases with the method of Dr. Delthil. At first he followed Dr. Delthil's directions exactly, but on account of the inconvenience produced by the black smoke-flakes which filled the room, he subsequently employed the rectified oil of turpentine alone. An ounce to an ounce and a half of this oil were burnt every three to five hours, the doors and windows of the apartment being closed. After half an hour the windows were opened in order to admit fresh air. Coming to the conclusion that the good achieved was due to the general and not to the local action of the turpentine, Dr. Schenker gave oil of turpentine internally, as he believed, to advantage, but as the vapors of burning turpentine were still used, it is very doubtful how much of the achieved good was due to the internal administration of the drug. The results are asserted to have been extremely encouraging. It is somewhat remarkable that recovery was secured in each of the four cases in which tracheotomy became necessary. Before and after the operation the vapors were steadily employed. The urine of each patient was examined every other day, but no albumen at any time was found, nor was the alimentary canal perceptibly affected. Dr. Siegel, of Stuttgart, has also recently affirmed the value of turpentine in the treatment of diphtheria.

Reports on Therapeutic Progress.

THE PATHOLOGY AND TREATMENT OF EPILEPSY.

An interesting discussion took place at a meeting of the New York Academy of Medicine, held March 3, 1887, on the above subject, which was opened by a paper by Dr. W. H. THOMSON, based on notes of sixty consecutive cases in private practice (*The Medical Record*, March 19, 1887). Dr. Thomson did not consider epilepsy as necessarily a convulsive disorder. He gave the following definition:

Epilepsy is a disease characterized by sudden and temporary loss of function on the part of one or more cerebral centres, an attack being induced by an afferent impression in every case.

The essential and invariable element in epilepsy is suddenness. It is the single truly

sudden disease. Other diseases may be rapid in their attack, but never sudden in the sense that epilepsy is. Among the neuralgias, angina pectoris may be an exception. Therefore all recurrent symptoms, whether sensory or motor, which are characterized by suddenness are ominous, because suggestive of epilepsy. Consequently *petit mal* was more real, as well as more objectionable, than *grand mal*.

Dr. Thomson then reviewed some of the theories that have been advanced with reference to epilepsy, as Hughlings Jackson's theory of the explosive discharge of nerve-cells from increased functional activity or increased nutrition; disturbance of Nothnagel's convulsive centre in the medulla; Robertson's upward discharge from this centre; Gower's involved theory, etc. The conclusion reached was, that all normal motor phenomena, except the purely voluntary, were directly regulated by the sensory department of the nervous system in all those respects which imply regulation of degree of the motor forces, and regulation of the time of their liberation and the channels through which these are liberated, whether singly or co-ordinated.

Given a moderate restraint of nerve-cells and centres by each other, and we have the status of bricks in an arch; but withdraw one brick, and the arch may behave as if shaken by an earthquake, when the disturbance all came from the sudden loss of the function of one brick.

The objection to the explosive sensory-motor theory was that it required more than one mechanism for the production of the same effect. The answer to the claim that Hitzig has produced epilepsy by limited motor excitation alone, and that it has been caused by irritation of the cortical motor area alone, etc., was that we do not get rid of the sensory-motor relations when the cranium is entered.

As to the *treatment of epilepsy*, Dr. Thomson emphasized the great importance of *perseverance*, for many obstinate cases had finally yielded. The first indication was to *improve nerve-nutrition*, and the most efficient agent that could be employed for this purpose was *cod-liver oil*. The prophylactic influence of this remedy was very noteworthy with reference to nervous diseases occurring in neurotic families, and particularly epilepsy.

The next remedy recommended for nerve-nutrition was *phosphorus*; the syrup of the hypophosphites (U.S.) acidulated by addition of one-fifth part of dilute phosphoric acid.

Total exclusion of butcher's meat for two years should be insisted upon; animal diet predisposes to convulsions and convulsive diseases.

Check rapid eating, because of the liability to irritate the convulsive centre in the medulla through the influence of crossing nerve-fibres.

The *bromides* are the most efficient remedial agents for the control of the attacks. These are to be aided by remedies which prevent them from impoverishing the blood, and they may be assisted very materially in producing their peripheral action by the use of the *red-pepper or mustard pack* before going to bed. Add a teaspoonful of red pepper to a pint of hot water, and wrap the body in flannel wet with a solution of this strength.

When muscular twitchings of the face occur during sleep, he regarded them as evidence of persistent cortical irritation, and advised the use of corrosive sublimate in doses of $\frac{1}{4}$ of a grain.

When symptoms referable to the digestive tract were present, *belladonna* with *oxide of zinc* should be used, pushing the belladonna to the production of its physiological effects.

When foul breath accompanies the gastric disturbance, *resin of turpentine* should be given as an antiseptic with belladonna.

The continuous use of *chloral hydrate* was beneficial. *Digitalis* was indicated when epilepsy was characterized by symptoms belonging to the genito-urinary tract, or by vascular symptoms.

The discussion was opened by Dr. L. PUTZEL, who, from a clinical stand-point, thought that the claim that epileptic attacks were always sudden could not be sustained, as it was not at all infrequent for prodromata, gastro-intestinal, mental, or otherwise, to precede the outbreak for two or three days. The suddenness of the attack could not be regarded as characteristic and the essential of epilepsy.

He had always understood that Jackson's theory referred to the explosive discharge of nerve-cells, not implying that it is limited to the motor nerve-cells. According to Jackson the visual disturbances in migraine are really epileptiform, and he claims that migraine belongs to that class of disorders. This proves that he does not limit the explosive discharge to the motor cells. Furthermore, Dr. Putzel could not understand what there was that led Dr. Thomson to believe that sensory impulses inhibit motor impulses; for a sensory impulse is generally a stimulus that sets a motor impulse into activity.

He thought that the paralytic attacks of *petit mal* were rare. The paralytic conditions were usually seen after severe motor convulsions, and were then probably due to exhaustion.

The pleural epilepsy which had been referred to by Dr. Thomson, produced by injections into the pleural cavity, did not strike him as valuable for the purposes of argument, because there was nothing to prove that the convulsions were epileptic. He did not think that the single manifestation of anything was epileptic; it was epileptiform, but not until it had been developed several times could it be regarded as true epilepsy. Convulsions from teething, which were probably due to local irritation, were not epileptic, but epileptiform, although the mechanism was probably similar to true epileptic attacks. In the one, however, there was a purely local lesion, which gave rise to reflex action by general brain-discharge; while there was in the other case some unknown condition of the brain itself, probably in the higher centres, which was the fundamental lesion—if what cannot be seen may be called a lesion—of epilepsy.

With regard to belladonna, he had used it in nocturnal epilepsy chiefly, in conjunction with the bromides. He agreed with Dr. Thomson that the disease was one of impaired nutrition, and therefore he prescribed cod-liver oil.

DR. PUTNAM-JACOBI referred to the question of rapid mastication, in connection with Lauder Brunton's directions that the fainting person be induced to sip cold water for the purpose of arousing him from syncope. According to Gowers, the aura, in about one-fifth of the cases of epilepsy, is of the special senses, which indicates that the lesion is cortical. The statement made by Dr. Putzel concerning paralytic conditions seemed to be contradicted by Gowers, who cites one or two cases in which there was a sudden loss of motor power.

DR. W. H. DRAPER said that he had listened to Dr. Thomson's paper with much pleasure, though he could not say that the author had thrown much light on an obscure subject by his ingenious theory, or that he had seriously shaken existing hypotheses as to the pathology of epilepsy. He believed that it was generally admitted that a large proportion of attacks probably had their origin in the convulsive centres of the cerebral hemispheres, and it was thus easy to account for the temporary aphasia and other transient psychical and sensory auras which

sometimes preceded or even occurred without the motor discharge.

The question of the determining cause of the phenomena of an epileptic attack, whether it is the result of vaso-motor spasm or not, is still undecided; and Dr. Thomson's hypothesis that it is a withdrawal of the control which the sensory functions of the nervous system exert over the motor functions does not appear to make the cause more clear. Dr. Draper agreed with Dr. Putzel in believing that it was not right to regard convulsions of peripheral origin, like the convulsions of dentition and gastro-intestinal irritation, as the exact parallel, pathologically, of idiopathic epilepsy, except in so far as they might both involve a sensory cause. He cordially concurred in what Dr. Thomson had said in regard to the treatment of epilepsy, and especially as to the importance of improving the nutrition of the nervous centres by cod-liver oil and tonics. He thought that, next to this, the most important point in the management of the disease was a careful study of the possible peripheral irritations which might provoke the attacks. These were very often found in errors of diet. He could not agree with Dr. Thomson, however, in what he had said about the exclusion of animal food from the diet of epileptics. On the contrary, he had been inclined to believe that the gastro-intestinal irritations which were the exciting causes of epileptic seizures were much more likely to follow the indigestions caused by overfeeding with the carbo-hydrates and fermented liquors. He preferred a diet of milk and animal foods for his patients, and had had excellent success in diminishing the frequency of the seizures by regulating the diet upon this principle. The next important point in the treatment of the disease was, of course, the administration of some drug which would diminish the extreme irritability of the convulsive centres; for this purpose no remedy had yet been discovered which equalled in certainty and in power the potassic bromide. Yet, despite all these measures, the experience of every physician would recall cases in which every form of treatment failed to control the disease, cases in which the patients preferred to have their fits rather than suffer the self-denials imposed by dietetic restrictions, and especially the misery of mental and physical hebetude caused by large doses of the bromides.

DR. E. D. HUDSON thought that the most plausible explanation of an epileptic attack was found in an initial condition of cerebral

anæmia, due to spasmodic contraction of the cerebral vessels, that gives rise to disturbance of the equilibrium of the nerve-force. He believed that convulsive attacks might become true epilepsy if allowed to persist. The best remedies at our command are the bromides.

DR. THOMSON said he never intended to imply that epileptic attacks had no prodromata. But a prodroma was not an attack. His reference was to the actual steps in the attack, and in those epilepsy was to be distinguished from all other diseases by its suddenness.

With regard to Hughlings Jackson's theory, he would say that he had understood that, while its author does not refer to motor discharge only, he specially dwells upon the motor discharge as the cause of the convulsive attack.

As to a sensory influence being stimulating in character, he should regard it as regulating the character by some kind of withdrawal or directing of motor impulse.

With reference to confounding all convulsions with epilepsy, his own observations had led him to the conclusion that he was unable to distinguish between convulsions of epilepsy in children and epileptic attacks occurring in dentition. He would be exceedingly obliged if either Dr. Putzel or Dr. Draper would tell him what an epileptiform convulsion was.

DR. DRAPER said that, in saying that a convulsion was epileptiform, he simply conveyed the idea that it had the form of epilepsy, but not the substance or nature of it. He thought there was an essential difference between epilepsy in its most aggravated form and an epileptiform spasm as the result of either extreme peripheral irritation or extreme central excitability.

DR. A. D. ROCKWELL then read a paper on

THE VALUE OF ELECTRICITY IN THE TREATMENT OF EPILEPSY,

in which he said that, if he were asked whether, under any circumstances, electricity alone was capable of curing epilepsy, his answer necessarily would be, exceedingly doubtful. Although he had never heard of a case that had been cured by electricity, he was not prepared, by any means, to say that such a result was impossible, or even highly improbable. If, however, he should be asked whether or not electricity was of any value in the treatment of epilepsy, he would unhesitatingly and confidently say that it was. He felt warranted, from his own experience, in

going even further than that, and was willing to say that in a certain proportion of cases in which the patients fail to receive more than temporary benefit from the bromides they may recover entirely when this plan of treatment is reinforced by the judicious and persistent application of electricity. What this proportion is must be a question for further and more general investigation.

Epilepsy is not, like chorea, frequently self-curative, and the books and journals say that benefit attends the use of a score or more of different remedies. Many of them are undoubtedly of value in treating the disease, and in some cases effect an absolute cure. Electricity has been found to act favorably upon the epileptic seizures; but what should more especially entitle it to consideration was its peculiar efficacy associated with other and more generally approved remedies, after these remedies alone had failed to give more than temporary relief.

The suggestion that the best results will be obtained in the treatment of epilepsy only when we call to our aid every measure that tends to develop vital power is one which commends itself to all. It is not alone, therefore, on the theory of the special influence on the nervous centres, or on cerebral circulation, that we employ electricity as an adjuvant to the bromides, but also because of its undoubted powerful constitutional effects. Above all, it is a *tonic*, and yet its therapeutical range is sufficiently wide to include both stimulating and sedative effects.

Therapeutically speaking, there are indications for the use of electricity in epilepsy other than those which call for its general tonic influence or its effects on the circulation.

An important indication for its use is the hyperexcitability of the nerve-cells in epilepsy. By submitting theoretical considerations to practical tests he had been convinced that this hyperexcitability, in some cases, has been held in check by the action of the galvanic current as readily as by the bromides. In several cases of *petit mal*, especially, he had observed that applications of the galvanic current to the cervical ganglia of the sympathetic produced precisely the same effect, in interrupting temporarily the frequency of the paroxysms, as did the bromide of potassium.

An illustrative case was cited, in which treatment, electrical and medicinal, was persevered in for fifteen years, and, up to this date, nearly four years from the last epileptic seizure, the patient—a woman who was 26 years of age when the first attack occurred—

had been entirely free from even a suggestion of epilepsy. From being hysterical, passionately unreasonable, and personally unattractive, the graces characteristic of the best feminine type had been either restored or come as a new growth. Three other cases also were reported, in which electricity, combined with other measures, had produced markedly good results.

Dr. Rockwell then presented the unsatisfactory side of the picture. The total number of cases of epilepsy which he had treated, with especial reference to the value of electricity, since 1874, was twenty-eight. All were in private patients. Ten abandoned treatment too quickly to be worthy of the slightest consideration in a statistical estimate of the value of any remedy. In three cases the treatment was persisted in sufficiently long to enable him to give electricity a fair trial, and he was compelled to admit that it seemed in no way to aid the bromides in controlling the disease. It was to be noted that in two of these three cases the seizure occurred in the daytime and while awake, and in the other the attacks took place both night and day.

Eight other cases, of which he had records, were under observation from six weeks to nine months. In all of them good effects of the treatment were manifest in a greater or less degree; and in two of them, one of which was under observation seven and the other nine months, the notable improvement was unquestionably due, in part at least, to electricity. Four of the remaining seven cases appeared in the present paper, and the others had been recorded in the *Medical Record*, April 6, 1878.

The conclusions which Dr. Rockwell had reached, after making observations for thirteen years, were:

First.—Electricity possesses a certain value in the treatment of epilepsy. It is not known, nor is it claimed, that used alone it can ever cure epilepsy. When, however, it is used in connection with the bromides its value is unmistakable, and a certain number of patients recover who otherwise would remain uncured.

Second.—The good effects of electricity are seen especially in cases in which the attacks occur in the night, although day attacks have been successfully controlled.

Third.—Central galvanization and general faradization have been the most efficacious methods employed.

Fourth.—When electricity fails to either cure or aid the cure, it is often efficacious,

by the method of general galvanization, in affording grateful relief from undefinable nervous symptoms recognized under the term neurasthenia.

Fifth.—The tolerance of bromides can be increased and bromic acne diminished by the systematic use of electricity.

Sixth.—Electrical treatment must be administered with care and judgment. All interruptions of the current should be avoided in central galvanization, as the shock is liable to hasten rather than prevent an attack.

THE TREATMENT OF SYPHILIS BY MERCURY.

At a meeting of the Medical Society of London, held February 21, MR. E. MILNER read a paper on the different modes of administering mercury in syphilis, and the indications for their application. He gave some of the results of his experience of twelve years' out-patient practice at the Lock Hospital, with a view of arriving at some definite conclusion as to what preparation of mercury should be employed in order as rapidly as possible to get rid of the visible signs of syphilis. In the majority of cases blue pill is as good as blue ointment and green iodide as Donovan's solution; but even in these cases he thought that more accurate and more careful observation in practice would render such an admission unjustifiable. He dealt with three of the most common methods of administration: 1. Some of the cases in which green iodide should be used. 2. Some of the cases in which inunction should be practised. 3. Some of the cases in which the vapor of calomel should be employed. Of all the syphilitic rashes, the most evident, most persistent, and perhaps the most difficult to combat, is the vesicular syphilide. It most frequently occurred in light-haired women, who drank large quantities of wine, as distinguished from spirits. The vesicular may be associated with an early tubercular syphilide, and this usually in dark-haired people during cold weather, and in the underfed and underclothed patients of anxious temperament. In the first of these two classes green iodide with Donovan's solution, in large doses, was most valuable; in the second class the inunction of the German preparation of blue ointment has excelled all other methods of treatment. In billiard-markers, some actors, barmaids, actresses, and commercial travellers, who drink freely and sit up late, the syphilitic rash is apt to become angry, excessively red, and marked.

In spite of the diarrhoea, give green iodide in large doses. Donovan's solution, with soda and iodide of sodium, will assist, the latter salt being better than the potassic salt. The keeping of late hours materially influences the character of syphilitic eruptions. These people often have a thick oily perspiration, which interferes with the nutrition of the skin and initiates the manifestations of syphilis; it was perhaps one of the causes of the so-called gouty character of the syphilide. Barmaids present the reddest and most angry syphilitic rashes, and the lesions are most difficult to treat. Such might be named "barmaid's syphilis." For these cases green iodide of mercury was the best preparation. In those who drink, and never take care of themselves, green iodide was next best to inunction, and would probably, under all the circumstances of the case, prove most efficacious. Green iodide of mercury is the most available remedy with patients who sit up late, who have light hair, and drink freely. The typical case for the green iodide would probably be the light-haired degenerated lady who sits up all night playing the piano at suburban parties, who eats but little, but refreshes herself frequently, and takes a little brandy before retiring to rest. The German ointment is less strong, contains more suet, and is harder and preferable to that of the British Pharmacopœia. It salivates severely less frequently, and produces a more permanent effect. Many cases of primary syphilis in healthy, abstemious, light-haired men will be benefited by mercurial inunction. Patients with fair hair treated in this country with inunction, though they may almost avoid syphilides, may suffer severely from a form of sloughing sore throat. Inunction in the late stages is a refuge for the destitute, but rarely it may give gratifying results. Large syphilitic testicles, secondary gummata, and syphilitic nervous disease may yield like magic to inunction. Inunction is most useful in the early stages with healthy, light-haired, abstemious patients with a primary sore, and the German ointment will almost certainly cure the distracted married man who has had syphilitic lumps for many years. To rapidly get rid of sores the local administration of mercury in the form of the vapor of calomel is of material assistance, whether the sore be the smooth, flat, indolent button, or accompanied by destructive ulceration of the glans penis. The vapor is also valuable in ulceration of the extremities, especially the legs, syphilitic in their origin, but frequently associated with a weak state of con-

stitution, or, more frequently still, associated with a too rapid or indiscriminate administration of mercury. In certain cases, where mercury cannot be administered internally, the vapor of calomel locally applied is of great assistance, as also in the red, angry, tubercular eruption on the forehead along the line of the hat-leather, and in the destructive ulceration of the fauces in late secondary syphilis.—*The Lancet*, March 5, 1887.

THE NUTRITIOUS VALUE OF PEPTONE ENEMATA.

EWALD, of Berlin, contributes an article to the *Therapeutische Monatshefte* for March, 1887, on this subject, which is as follows:

In spite of manifold investigations regarding the value of peptone injections, the use of these agents for nourishing the sick through the mucous membrane is not an accepted usage, probably because the experiments upon this point were made upon animals or upon healthy men, and investigations upon diseased men have been so recently made. It cannot be denied, however, it is indeed highly probable, that invalids, especially those with affections of the digestive organs and impaired assimilative powers, stand in entirely different relationship regarding susceptibility to these agents than do healthy organisms.

The present investigation was made under all possible cautions upon three patients aged respectively 57, 34, and 32 years. The first patient had paralysis of the left arm after apoplexy some time before, but was otherwise healthy, the body weight at the commencement of the treatment being one hundred and five pounds. The second patient was partially demented, and while having no direct lesion of any organ which could be discovered, yet was anæmic and poorly nourished, the body weight being also one hundred and five pounds. The third patient had a severe neurosis of the digestive tract. She took the smallest amount of nourishment possible, which was generally rejected by emesis. She had been for some time treated by nutrient enemata, and was bedridden, her weight being ninety-five pounds. The estimation of the solids in the urine was performed in accordance with the methods of Pflüger and Boland; the solid matter of the fæces was estimated by the method of Kjeldahl. The materials used were Kemmerich's flesh peptone, Merck's caseine peptone, an emulsion of raw eggs, and eggs prepared by emulsifying eggs with fifteen per cent. HCl

(pure) and pepsin (two to four scruples) for twenty-hours, making weakly peptonized eggs. The treatment was administered in periods of one, three, or five days, and was regularly continued for three months. Preparations of egg were included for the reason that the preparations of peptones commonly purchased contain but a minimum of genuine peptone, while the experimenter, by making his own mixture, could be assured of the material. The results were as follows: Single doses of purchased peptones, in quantities of six and one-half, ten, and twelve and one-half drachms, had but a transient and unreliable effect upon tissue-changes. Once only was observed a decided increase in the nitrogenous matters in the urine; in other experiments the increase was very slight, in some cases it was entirely wanting. An increase in the amount of urine followed all the enemata which were given, an increase too great to be accounted for by the solution of the peptones taken and the amount of water injected, so that the substances ingested had an evident influence in producing diuresis, which was probably dependent upon the various salts which the peptones contained.

The great variations in the effect produced by single injections teach us that a series of observations is needed to arrive at reliable results. In the case of the third patient, the series of injections was continued three months, in periods of three and five days. Ten, twelve and one-half, and eighteen and three-fourths drachms of the purchased material was used, and the nitrogenous matter corresponding to four or six eggs. The result in the production of nitrogenous excreta was greatest after the ingestion of Merck's casein peptone; the same in amount after the use of Kemmerick's peptones and prepared eggs, and sank to its lowest limit when neither peptones nor eggs were given. For example, the excretion of nitrogenous matter, after the daily ingestion of two and one-half drachms of nitrogenous food by the mouth and by casein peptone enemata, was two and one-third drachms; after using two and five-sixths drachms of nitrogenous food by egg enemata, one and five-sixths drachms of nitrogenous excreta; after two and two-thirds drachms of nitrogenous food in flesh peptone enemata, one and one-half drachms of excreta (nitrogenous); while the ingestion of one and one-third drachms nitrogenous matter of ordinary diet, of which one pint of milk, without preparation or addition, was given as an enema, returned one or one and one-fourth drachms

of nitrogenous matter in the excretions found in the urine,—that is, a comparatively close correspondence between the quantity of nitrogenous matter ingested and excreted was observed when ordinary diet only was taken. Especially evident was the lessening in the excreta which succeeded each marked increase.

Much more noteworthy, however, than the metabolism of peptone was the gain in nitrogenous matter which the organism acquires, which is assimilated by the tissues, and therefore is lost from further estimate. In these results the gain in nitrogenous matter was least after the use of Merck's casein peptones; the gain was greatest after the use of peptonized eggs; between these extremes was flesh peptones and raw eggs, not prepared, while the omission of peptones, especially eggs, was followed by a loss, which succeeded most markedly immediately after the greatest gains. As illustrating these observations the following were noted: After the ingestion of two and one-half drachms of nitrogenous matter in casein peptone the gain in nitrogenous matter retained was but six grains in five days; after the ingestion of two and five-sixths drachms of prepared eggs, four and one-third drachms of nitrogenous matter was gained; when two and two-thirds drachms of Kemmerick's peptones were given, two and five-sixths drachms of nitrogenous matter was gained; when two and one-third drachms of raw eggs were administered, more than three drachms of nitrogenous matter was gained; with the giving of four scruples of nitrogenous matter there was a loss to the extent of two and one-third drachms in five days. These amounts, like those preceding, are not strictly accurate in showing an equal return of matter ingested, but they vary within certain limits, which evidently depend immediately upon the favorable or unfavorable peculiarities of the individual; so that, for example, on a second trial with casein peptone much better results were obtained; in five days an increase of two and two-thirds drachms followed the ingestion of two and one-half drachms of nitrogenous food. The casein peptone never equalled in food value the eggs and flesh, although until it is possible to complete chemical changes in the body more accurately too great stress should not be laid upon the apparently unequal amounts of nitrogenous gain retained.

The following facts were demonstrated from these experiments, with no room for doubt:

First.—The power of the rectum to absorb is undoubted: the amounts, however, which are absorbed vary greatly from influences not to be controlled and peculiar to the individual, so that a purely physical or chemical action, independent of nervous influence, which can be produced by the necessary means at will, does not exist.

Secondly.—The appropriateness of an albuminoid for rectal absorption is not dependent upon its richness in genuine peptone. Eggs which contain the smallest quantity of peptone are as readily absorbed, and even give a greater gain to the organism than peptones which have a double or quintuple amount of contained peptone.

Thirdly.—We are able to produce with unprepared eggs, and still better after preparation with hydrochloric acid and pepsin, the same results which are obtained with purchased peptones, and at about one-half the cost.

THE EFFECT OF HYDROCHINONE ON URINE AND UREA.

DR. ANTAËFF, working in Professor Sushchinski's pharmacological laboratory, has recently investigated the effect of the presence of hydrochinone on the alkaline fermentation of urine and on urea itself. Hydrochinone is represented by the formula $C_6H_4(OH)_2$, being, in fact, benzole in which two atoms of H are replaced by hydroxyl; it is isomeric with paracatechin and with resorcin. Mering found it in the urine after arbutin had been given, and Baumann and Presse in that of persons who were taking carbohc acid. Dr. Antaëff found that when two per cent. of hydrochinone was added to fresh urine the latter remained entirely free from alkaline fermentation. After twenty-five days no cloudiness or precipitate had formed; there was no ammoniacal odor, the smell being just like that of fresh urine; the reaction, too, was acid. When only one per cent. of hydrochinone was added, some deposit formed after a time, but there was no ammoniacal odor, and the reaction only became neutral. Observations were then made on solutions of urea. To one hundred cubic centimetres of distilled water were added one gramme of urea and one gramme of hydrochinone. After twenty-four hours seventeen per cent. of the urea had been decomposed. When the hydrochinone was omitted, only one per cent. of urea was decomposed in the same time. Again, when larger quantities of urea were present, hydrochinone, in the same

quantity as before, exerted a still greater effect in increasing the decomposition; thus a three per cent. solution of urea lost 0.2 per cent. of its urea, but when hydrochinone was present it lost 13.5 per cent. The solutions of urea with hydrochinone turned a light cinnamon color, which became darker on standing. The destruction of urea by hydrochinone was believed by Dr. Antaëff to be due, not to a fermentation process, but to a chemical action of hydrochinone upon urea. Dr. Dianin suggests that the action may be analogous with that of acids on urea, which cause it to break up into ammonia and carbonic acid, with this difference, however, that hydrochinone probably forms a compound with the ammonia as it is disengaged, which is not easily decomposed by hypobromite of sodium. This theory will also account for a certain deficiency in nitrogen which was always observed in azometric determinations of urea in solution with hydrochinone.—*Lancet*, April 16, 1887.

THE ACTION OF SPARTEINE.

VOIGT and LEO have through recent papers added to our information as to this alkaloid. According to the analysis of their papers published in the *Med. Chron.* for April, 1887, Voigt found that sparteine in doses of $\frac{1}{8}$ to $\frac{3}{8}$ grain, in a series of cardiac and other diseases, stimulated the heart, increased the contractions, and raised the blood-pressure. It acts quickly, and its action lasts often over twenty-four hours, during which time the effect can be increased by a repeated dose. A pause of a few days after continuous administration is useful, as the drug acts the more forcibly afterwards. He finds it to be a diuretic, but not one of first rank. Toxic symptoms, very seldom observed with doses of 1 to 4 mg. ($\frac{1}{8}$ to $\frac{3}{8}$ grain), were faintness, headache, palpitation, and uneasiness, which soon disappeared, even when the use of the drug was continued. Voigt would recommend sparteine for therapeutic use,—1, in valvular disease with failing compensation; 2, in valvular disease without faulty compensation, as a tonic and sedative; 3, in weak action of the heart without valvular disease; 4, in pericarditis; 5, as an adjuvant to digitalis.

Leo exhibited sparteine in doses of 0.1 gm. ($\frac{1}{10}$ grains) every two hours in twenty-four cases. In only nine of these was there any objective result definitely traceable. In the remaining fifteen cases, eight showed subjective improvement, and in seven no result

whatever was perceptible. In the first nine cases there was very marked diuresis. The drug did not influence the blood-pressure materially, and on this point the author differs from Germain Sée, who placed digitalis and sparteine side by side. He ascribes the diuretic action of the drug to stimulation by it of the renal epithelium. He found the drug to have a marked action upon the heart in relieving palpitation, pain, and dyspnoea. In the majority of cases, where relief was afforded, there was no evidence of any controlling of the heart's action. He finds sparteine most active when given shortly after a course of digitalis. No symptoms of poisoning were observed. The author thinks that sparteine is indicated when diuresis is required, and will be principally useful in cases of cardiac disease with failing compensation. It is noteworthy that, though Leo has administered the drug in doses a hundred times greater than those given by Voigt, yet he seems to have been less successful in his results.

RECENT TESTS FOR SUGAR.

In addition to the ordinary clinical tests for sugar, such as copper sulphate and potash, potash alone, indigo-carmin and others, two new reactions have been described which are stated to be more delicate than those now in use. The first of these, in point of time, was introduced by Fischer, and had been utilized by Von Jaksch in clinical investigations. It consists in placing a small portion of hydrochlorate of phenyl hydrazine with twice the quantity of sodium acetate in a test-tube, which is then half filled with water and warmed. After adding an equal volume of the solution to be tested, the mixture is boiled for twenty minutes, when, on cooling, yellow crystalline needles of a compound of glucose and phenyl hydrazine (phenyl glucosazine) are deposited. These crystals have a definite melting-point of 204° to 205° C. If the quantity of sugar is small, the microscope may be required to detect the characteristic crystals. By this test, which is a very delicate one, Von Jaksch has investigated the occurrence of sugar in many morbid conditions. In normal urine a positive result was never obtained, though the small number of cases examined did not justify a refutation of the statement that small quantities of sugar are present in normal urine. The test is a very convenient one to apply to the small quantities of sugar which are sometimes present in the urine in cases of brain-tumor and liver-disease; but the most

interesting results were obtained in certain cases of poisoning. Thus, in carbonic oxide poisoning, though the fact of the presence of sugar in the urine has often been stated, no accurate chemical investigation has been made of the matter. The question is, however, settled by the very positive results obtained by means of the phenyl hydrazine test. Sugar was found in all the three cases of poisoning which came under investigation. It was also found in two cases of asphyxia, and in one of deep chloroform-narcosis, and in the urine of a patient taking large doses of salicylate. The last observation is an interesting one, as, though it is well known that the urine of patients taking salicylate reduces Fehling's solution, it is not certain whether this reduction is due to glucose or to a salicylate excretory compound. The phenyl hydrazine test will no doubt be found useful in deciding whether sugar is present or not, when the ordinary clinical tests give a doubtful reaction.

The second test for sugar has been introduced by Molisch, and does not appear to be so accurate as the one just mentioned. It consists in adding two drops of a fifteen to twenty per cent. solution of naphthol in alcohol to the liquid to be tested, and then an excess of strong sulphuric acid, which causes a deep violet coloration; if water be now added, a deep violet precipitate is formed. If thymol be used instead of naphthol, a carmine-red precipitate is produced. The test was introduced by Molisch, and Seegen has stated that it is given by all proteid bodies. The reactions are, however, different, since the proteid precipitate is soluble in strong hydrochloric acid, while the sugar one is not. The reaction would thus have disadvantages in a clinical application if albumen were present. Molisch states that by its means he has been enabled to confirm Brücke in finding small quantities of sugar in normal urine.—*Brit. Med. Jour.*, February 26, 1887.

A METHOD OF APPLYING PLASTER OF PARIS IN CASES OF FRACTURE OF THE LEG.

DR. C. R. ILLINGWORTH describes, in the *Provincial Med. Jour.* for April 1, 1887, a method of applying plaster of Paris in cases of simple fracture of the leg, which he has found easy and efficacious. The fracture having been carefully set and well-padded Cline splints applied, he waits for a few days to see that no inflammatory action exists at the seat

of the injury. If it supervene, a lotion of acetate of lead and tincture of belladonna will answer well. As soon as all inflammation has subsided (during the treatment of which the use of the outer portion of the splint will generally suffice) he applies the plaster to the inner side of the leg first, on a piece of lint shaped to the leg and foot, to prevent contact with it. A paper pattern of the inner side of the leg and foot from below the knee to the sole is then cut, which shall represent about a quarter- or half-inch less than half the circumference. Three, or at the most four, pieces of lint are then cut to the pattern, and roughly stitched together. The larger (protective) piece of lint having been laid on the leg and foot while held by an assistant or two, on the outer Cline, the lint is saturated with plaster of Paris mixed with an equal weight of water, and bound to the outer Cline with a broad fine calico bandage. For this purpose one pound of plaster (to one pint of water) is enough. The limb is then laid on the outer side as before, and steadied with sand-bags for a day or two days. The broad bandage is then unwound or cut off with scissors, and the outer Cline removed, while the leg is supported on the inner plaster-splint, and the process repeated on the outer side of the leg. By this method all unnecessary movement of the fractured limb is avoided. When the second or outer portion has been laid on, Dr. Illingworth finishes bandaging with muslin bandages impregnated with plaster of Paris and moistened with water before being applied.

NEW TREATMENT FOR PHTHISIS.

A new method of treating phthisis has been proposed, but apparently as yet but slightly tried, by PROFESSOR KREMIANSKI, who read a paper on the subject at the recent Moscow Medical Congress, which provoked a good deal of discussion. The idea is based, firstly, on the fatal effect of the most dilute solution of aniline on Koch's bacillus; and, secondly, on the fact that aniline seems to be but slightly, if at all, poisonous to the human body. Professor Kremianski proposes to introduce aniline into the lungs, and, indeed, the circulation generally, by inhalation, so that the phthisis bacilli should be bathed in a very dilute solution of aniline, wherever they may be. This, he thinks, would kill them, and render even pulmonary cavities free from bacilli, so bringing them into the condition of healthy granulating ulcers, which may be ex-

pected to cicatrize. A committee has been appointed, including Professors Subbotin and Ostroumoff, who expressed themselves at the meeting as strongly opposed to the plan, for the purpose of observing Professor Kremianski's proposed experiments in one of the Moscow hospitals. Two cases in which the aniline treatment had been successfully tried were detailed. A lad of 18, who had undoubted phthisis, was ordered a 4-drop dose of aniline (but took by mistake three times the proper quantity) combined with nux vomica, mint-water, and antifebrin, his diet being good, including dried meat, kvas, and oranges. He was also given inhalations of atomized aniline. A remarkable change took place almost immediately, all the râles disappearing; his temperature, respiration, and pulse becoming normal. His skin, however, assumed a slightly blue tinge, but whether this was as permanent as the cure is represented to have been is not stated. The second case was a complicated one, there being tubercular peritonitis and meningitis, together with typhoid fever, present at the same time as pulmonary phthisis. Aniline inhalations, washing out the pulmonary cavities with corrosive sublimate and antifebrin, were employed, together with a special acid diet, as in the other case. Here, too, the results are said to have been remarkably good, the bacilli disappearing from the sputum, and the patient regaining his health entirely. No mention is made in the abstract published by the *Vratch* of any change of color in this patient's skin. Among the various replies that were made to Professor Kremianski, Dr. Zakrzhevski, of Helsingfors, remarked that, admitting the facts as stated, still there was nothing to show that the aniline had been the cause of the cures. He himself had had surprisingly good results in phthisical cases, the disease becoming completely arrested by simply giving increased nourishment and prescribing antipyrin.—*The Lancet*, March 5, 1887.

ABSORPTION THROUGH THE SKIN.

RITTER and PFEIFFER (*Berliner Klin. Woch.*) have repeated the experiments which have been made on this much-disputed topic, and their results serve to strengthen the doubts which others have before expressed as to the capability of the skin to absorb the substances which have been long used, probably following up a false analogy with the effects of mercurial inunctions, with the intention of producing their constitutional effects by their transmission through the skin into the gen-

eral blood-current. The method which they employed consisted in rubbing well into the extensor surface of a perfectly healthy arm or leg about half an ounce of a salve containing the substance under investigation, and then keeping the skin firmly covered for twenty-hours with a protective bandage, so as to prevent any possible absorption by the lungs. The urine was collected for twenty-four hours and examined, both with and without previous concentration, for the presence of the drug. By these means it was found that a ten per cent. iodide of potassium salve transmitted the salt through the skin only once in five different cases, and then only after being used for four days,—that is, in other words, only after the skin had been irritated and its continuity destroyed by the prolonged action of the fatty acids derived from the decomposition of the lard.

Salicylate of sodium applied in the same way never showed the slightest trace of its presence in the urine.

Salicylic acid, on the contrary, invariably gave its characteristic color test with ferric chloride within a few hours after its application. This is easily explained by its well-known action in softening the epidermis and rendering it permeable. If iodide of potassium be applied to a spot previously treated with salicylic acid, it quickly passes into the organism and becomes detectable in the urine.

In a series of parallel experiments made with the view of testing the reputed power of Liebreich's lanolin in assisting bodies incorporated with it to penetrate the skin, the authors were unable (in common with the majority of other experimenters) to perceive that it possessed such power in the slightest degree. [Its physical properties are, however, undoubtedly useful as a salve base.]

Ritter repeated also the experiments which he had previously carried out in order to test the capability of the skin to absorb substances which were sprayed on to it in watery solution. Röhrig, and later Juhl, had asserted this apparently paradoxical action really occurred. Ritter, however, after carefully excluding all possibility of entrance of the fluids into the system through the mouth or respiratory passages, was utterly unable to find in the urine the slightest trace of the salicylate of sodium or iodide of potassium with which he experimented. He therefore confirms the result of former experiments of his, that the normal skin is not permeable to substances in spray solutions.—*American Journal of Pharmacy*, April, 1887.

THE THERAPEUTIC USE OF IODOL.

PICK gives the results of his use of this agent in the clinical wards of the hospital at Prague. He finds that it resembles iodoform, but possesses the great advantages of freedom from odor, unpleasant after or attendant effects, and its adaptability to internal use. It is a yellowish-brown powder, soluble in absolute alcohol, one to three; in ether, one to one; in water, one to five thousand. The writer employed it as powder; gauze; iodol ether (ten to twenty per cent.), which was especially useful in spray; iodol-ether colloid, one to five or ten of iodol; iodol ointment, with lanolin, five and ten per cent.; and iodol paste, made by adding a few drops of alcohol or glycerin to iodol.

Regarding its elimination and constitutional effects, iodine was found in the urine and saliva in a case in which iodol had been packed into the cavities of buboes; symptoms of iodism were also present in this case; other examinations failed to reveal its presence in the secretions after use.

In its effects when used by internal administration it differed markedly from potassium iodide in that it was slowly absorbed, and only after four and one-half or six days was entirely absent from the secretions; potassium iodide, on the contrary, is quickly absorbed and excreted in one and one-half or two and one-half days.

The writer used iodol in the following diseased conditions:

1. Simple catarrh and blennorrhagic catarrh of the vagina and cervix, with erosions and inflammation of Bartholini's glands; cleansing with sublimate solution, spray of iodol ether, tamponing with iodol gauze. Result, good. Iodol could not, however, be used in the urethra.

2. Simple and also sclerotic ulcerative processes. Iodol does not check ulceration in its virulent form, it does not hinder a process of sclerosis nor effect absorption, but it markedly hastens healing. It was used in spray, powder, or gauze.

3. Condylomatous processes were hastened in their healing by iodol spray; the absorption of the infiltrate was aided by mercurial plaster.

4. Suppurative adenitis; incision and cutting the abscesses; disinfection with sublimate solution; filling the cavities with iodol and iodol gauze. The first bandage applied remained five days without renewal; the second, eight days. The time generally consumed in healing was sixteen days; in indo-

lent buboes, iodo ether, collodion, poultices, and injections of unguentum cinereum, in quantities as great as 30 grains, in the thighs and hypogastrium.

5. Gummata and gummous ulcers: the former were treated by iodo ether collodion, iodo-lanolin ointment, and poultices; the latter by iodo in powder. Iodo was well borne when given internally in doses as great as 30 or 45 grains daily, which rarely produced diarrhoea, and in only the mildest degree intoxication.

In view of its peculiar absorption and elimination the writer gave for two days in succession, morning and evening, $\frac{1}{4}$ to $\frac{1}{2}$ grain in capsules, and repeated these doses first on the same day of the following week, his purpose being to allow one or two days to be free from ingestion of iodine. Iodo is preferable to potassium iodide in that the action of its iodine radical is more prolonged, not intensive. When a rapid and energetic action of iodine is desired, potassium iodide should be given.

6. When used for various non-venereal processes, as chronic ulcers of the feet, scrofulous gland abscesses, lupus after scarification and curetting, iodo acts as iodoform, but forms no crust.—*Therapeutische Monatshefte*, No. 1.

CLOTTAGE OF THE URETERS.

At a meeting of the Medical Society of London, held March 14, 1887, MR. HURRY FENWICK submitted for criticism an operation which he had termed clottage of the ureters. The procedure consisted in an attempt on the part of the surgeon to block or to cork up a ureter with clot. He argued from statistics that it ought to be performed in those cases where the surgeon has to combat profuse and ungovernable hæmaturia from a kidney hopelessly crushed by an accident or affected with advanced carcinoma; that it was a conservative operation; and that it ought to rank immediately before the operation of nephrectomy. The procedure consisted in introducing into the bladder the author's ureter-aspirator (GAZETTE, Nov. 15, 1886, p. 841, Suction of the Male Ureters). The ureter of the damaged kidney is then sucked into the eye of the instrument, and the blood-clots in the ureter. Light pressure is now made with the beak of the instrument against the opposing finger in the rectum, and the ureter is thereby tightly nipped, thus giving time for the clot to collect a little in the pelvis of the kidney. A case in which the operation was

successfully performed was related, of a man aged 51, with right renal carcinoma, whose hæmaturia, of thirteen months' duration, had been profuse and intermittent, but after the operation was clear to the day of death, six months later. No necropsy could be obtained.

MR. JACKMAN showed his instrument for nipping the orifice of the ureter, and explained its use.

MR. MORRIS quoted cases which showed that plugging of the ureter with clot was followed by enormous distention of the kidney by blood.

MR. R. W. PARKER and MR. BRUCE CLARK advocated direct surgical treatment of the kidney, provided hæmostatics failed.

MR. BERNARD PITTS said the danger was usually from peri-renal or intra-peritoneal extravasation of blood, rather than from its escape into the bladder. He asked if this instrument could be used to remove a clot from the ureter.

MR. FENWICK, in reply, said that clots were usually adherent to the ureter, and could not be removed by suction.—*The British Medical Journal*, March 19, 1887.

THE NEW "SPECIFIC" FOR DIABETES.

According to the Paris correspondent of the London *Lancet* (March 26, 1887), DR. MARTINEAU gives full details in the last number of the *Annales Medico-Chirurgicales* of the treatment advised by him in diabetes. It was in consultation with the late Professor Rouget that he learned the formula which he now publishes with so much confidence. The patient in question had been the subject of diabetes for some years, and was suffering at the time from cerebral hemorrhage. Dr. Rouget proposed that they should not modify his diet in any way beyond restricting in a slight degree the use of farinaceous food, fruits, and sugar, and that he should drink during meals and in the intervals of thirst arsenicated lithia water, prepared as follows: In the upper part of a Briet apparatus of one litre for making aerated water were to be introduced twenty centigrammes of carbonate of lithium, and a tablespoonful of the following solution: arseniate of sodium, twenty centigrammes; distilled water, five hundred grammes. This water to be drunk at meals mixed with wine, and the contents of the recipient to last for three meals. Before commencing the treatment the urine was found to contain sixty grammes per litre of sugar, being two hundred and twelve grammes for

the quantity voided in the twenty-four hours. Three weeks later, on October 12, two litres, instead of three and one-half, represented the daily secretion of urine, and the quantity of sugar twenty grammes per litre. On October 29 there were one and one-half litres of urine, and the amount of sugar eleven grammes per litre. On November 14 the proportions had fallen to one litre of urine containing four grammes of sugar. On December 1 no sugar could be detected, and the daily average of the urine was one litre. The patient died four years later of uræmia caused by renal disease, and up to the time of his death no sugar had ever been found in the urine. Dr. Martineau gives two other cases in illustration, in which the treatment has kept the glycosuria in abeyance for six and five years respectively. In a third instance no sugar has been seen for six months. In all the patients with whom the treatment was successful there were, says Dr. Martineau, arthritic symptoms, either in the form of biliary or renal lithiasis, of articular manifestations, or of cutaneous eruptions. In the only three cases of failure there was no arthritism, but herpetic symptoms existed in the form of "nervovism" and skin-eruptions. The disappearance of sugar from the urine is attributed by Dr. Martineau to the action of the lithia upon the glycogenic matter, which it helps to transform into glucose, and thence into carbonic acid and water. It is the presence of lithia that also explains the action of those natural mineral waters which are useful in diabetes. Taking for granted that the results are as stated by Dr. Martineau, it is somewhat remarkable that he should fall into therapeutic superstition, when there is a much more adequate physiological explanation. In all his successful cases the quantity of drink was restricted to a quart during three meals, whereas in the unsuccessful case, which is given for the sake of comparison, the patient drank three litres and voided an equal quantity of urine in the twenty-four hours. The late Dr. Hyde Salter found abstinence from liquids at meal-times the most useful of all treatment for asthma, and obstructed respiration is given by Pavy as a cause of diabetes, Brunton allowing that it is produced by deficient oxidation, which comes to the same thing. There is a group of allied affections characterized by the retention of the products of imperfect oxidation, and by functional disturbances of different kinds resulting therefrom, the cause and effect having a reciprocal action. Gout and nervous depression, obesity and imperfect respiration,

are familiar examples. In these cases, as in rheumatism and other morbid conditions of the same kind, everything that promotes oxidation and excretion is of capital importance. Abstinence from alcohol and the use of the Turkish bath are valuable means to this end, but total abstinence from alcohol, with a strict limitation of fluids, is the most potent of all. Unfortunately, it is extremely difficult, most especially in diabetes, to carry out such restrictions. If, however, lithia as administered by Dr. Martineau does enable diabetics to abstain from liquids, he may be congratulated upon having made a valuable contribution to practical medicine.

THE USE OF ACONITINE IN THE TREATMENT OF NERVOUS DISEASES.

At a meeting of the Medical Society of the County of New York, held January 24, 1887 (*New York Medical Journal*, April 16, 1887), DR. E. WAITZFELDER described the physiological action of the amorphous and crystalline forms of aconitine. The drug, he said, seemed to have a double action on the nerve-centres,—first, that of irritation; second, that of subsequent paralysis. In the treatment of diseases of the nervous system, it was in neuralgias especially that it was of service, and, after citing evidence in this direction from different authorities, he said his own experience with the drug in this class of nervous affections had been equally satisfactory. He had succeeded in curing some patients and relieving others, who had suffered from facial neuralgia for a varying length of time. He had found a combination of aconitine and veratrine, used externally, to act better than aconitine alone. Caution should be observed in applying it near the eye, and over cuts and bruises, as a poisonous amount might enter the system. He had employed aconitine in three cases of chronic sciatica; in two with decided benefit; in the third with no apparent benefit after a month. In the treatment of pachymeningitis, whether syphilitic or not, he had occasionally observed benefit. A marked example was related, in which a woman was relieved of pain within three days, after anti-syphilitic treatment alone, long continued, had been ineffectual. There was a history of syphilis. The use of aconitine was almost always followed by some relief in such cases, but not always so soon. He had used it for agonizing headache from tumor in two cases, but without giving relief. *In two cases of exophthalmic goitre no effect upon the tumor or the

eyes was observable, but the patients said they felt better after the use of the drug. It was of benefit in active congestion of the brain with increased blood-pressure from excessive action of the heart. Here it was combined with bromide of potassium. In insomnia from business troubles it was of benefit in connection with small doses of bromide of potassium. In selected cases, carefully watched, it was useful for hyperæsthesia from spinal irritation, and in cases in which there were doubts as to commencing myelitis.

EFFECT OF MASSAGE ON EXHALATION FROM THE LUNGS AND SKIN.

DR. STABROVSKI has published a series of laborious researches made with a view to determine the effect of massage upon the pulmonary and cutaneous exhalation. They were carried out in Professor Manasseïn's wards in St. Petersburg on fourteen persons, nine of whom were in good health, and the remaining five convalescent from various acute diseases. In each case the duration of the observations was ten days, during the first five of which massage was practised. Deep kneading was practised for the first two days, after which the body was washed over with a wet sponge to remove the fatty matter adherent to the surface of the skin. During the next two days deep rubbing was practised, and then the wet sponge used again. On the fifth day deep rubbing with the dry hand was practised. The massage took place at 10 A.M., except in two cases, where, it was performed at 7 P.M., with the object of observing its effect on nocturnal perspiration. The sittings were of an hour's duration. The results in the different cases were discordant. In five cases there was an increase in the pulmono-cutaneous exhalation and a diminution in the amount of urine, the increase occurring shortly after the massage, so that when this was practised in the morning the perspiration was increased during the day, but became normal during the night. Similarly the quantity of urine fell during the day and rose again at night. In three cases the massage increased the quantity of urine and diminished the pulmono-cutaneous exhalation. In the remaining six cases both the urine and the pulmono-cutaneous exhalation were increased during the period of massage. The general effect on the pulse was to lower it some ten or fifteen beats. No alteration appeared to be produced in the rate of respiration.—*Lancet*, March 26, 1887.

THE PROTECTION OF THE PERINEUM WHILE THE FŒTAL HEAD IS PASSING.

DR. D. BERRY HART describes in the *Edinburgh Medical Journal* for April, 1887, the plan which he teaches for supporting the perineum, and which he believes to fulfil its purpose. It comprises the consideration of the three different points :

1. *The relations of the uterus and its contents when the normally rotated fetal head is beginning to distend the perineum.*

At this period of the labor, the lower uterine segment, cervical canal, and pelvic floor have been canalized by the retracting uterus elongating and pushing the foetal contents downwards. The whole foetus is compressed and packed together, with the chin flexed on the sternum, and the occiput leading. The perineum or sacral segment is being driven back, its lower end elongated and thinned, and the vulvar cleft, chiefly in its lower part,—i.e., below the level of the vestibule,—greatly distended. Uterine retraction sets up in the foetus and retained liquor amnii a general-contents-pressure, which is distributed over that part of the skull periphery lying below the girdle of resistance. The diameters of the girdle of resistance will vary greatly, according to whether the occiput or sinciput dips. In the latter case the antero-posterior diameters will be increased, and the risk of tear augmented in like proportion. The demonstration of this belongs to elementary obstetrics.

In taking (2) *the consideration of how the fetal head should pass the perineum so as to have a minimum of tear*, Dr. Hart first points out that the term extension of the head, as the fourth consecutive movement of the labor mechanism, is a most misleading one. It implies what he denies,—that the chin leaves the sternum while passing the perineum ; and that during the anterior fixation of the occiput under the pubic arch, antero-posterior and increasing diameters of the foetal head form the antero-posterior diameters of the girdle of resistance. Dr. Hart denies *in toto* that the chin leaves the sternum, and he holds that this fixation of the occiput and descent of the sinciput is not the best or normal mechanism. The best mechanism to avoid tear is for the occiput to lead, for the head to be driven on by a steady movement of translation, any rotation on a biparietal axis so taking place as to favor occipital dipping and never dipping of the sinciput. It is easy to see how the erroneous idea of extension arose. The at-

tendant, while the patient lay on her left side, watched the passage of the foetal head from behind, saw more of the anterior portions of the head appear, and accounted for it by extension.

The author then passes to (3) *a description of how the medical attendant can best guard the perineum, so as to avoid undue tear.*

All the attendant can do, apart from the familiar means of relaxing perineal spasm by chloroform and hot applications, is to prevent the sinciput being forced down in advance of or faster than the occiput. He restrains the foetal head from passing too rapidly. He thus has always to get the occiput to lead, and to get it fully born first if possible. The best way of doing this is as follows:

With the patient lying, of course, on her left side, the attendant places the thumb of his right hand, guarded by a napkin soaked in hot sublimate, in front of the anus, and presses it gently there. The pressure is not in the direction of a line joining his thumb and the pubic arch, but nearly in that of the axis of the pelvic outlet. By this, descent of the sinciput is hindered, and that of the occiput favored. When the latter is beginning to pass under the pubic arch, the fingers of the same hand are placed between it and the apex of the arch, so that when the occiput has cleared the arch the fingers are passed towards the nape of the neck, and the head thus grasped in the hand, the thumb lying over the sagittal suture. This gives one complete command over the head which is now engaging in the diameters between the nape of the neck and forehead and face, and allows the whole passage with as little tear as possible.

QUILLAIA SAPONARIA AS AN EXPECTORANT.

In the *Centralbl. für Klin. Med.*, No. 30, 1885, Dr. Kobert published a paper, already referred to in the GAZETTE, on the root of a South American tree, *Quillaia saponaria*, to recommend it as a valuable substitute for the root of *Polygala senega*. The active principle in both of the plants is a glucoside body, saponine. According to Kobert,—1. Quillaia contains five times as much of saponine as senega does. 2. Quillaia is rich in sugar, and is free from the substance to which the bad taste of senega is due. 3. Patients tolerate quillaia better than senega. 4. Quillaia but very seldom gives rise to vomiting and diarrhoea. 5. The drug possesses a decided expectorant action. Kobert's statements were

fully confirmed by the observations of Dr. Goldschmidt (*Aerztl. Intell. Blatt.*, No. 48, 1885), who had administered quillaia in thirty cases of pulmonary disease, and found that the drug may be successfully used both in cases of very profuse and very scanty expectoration. Following the example of Kobert and Goldschmidt, Dr. A. MASLOVSKY, of Professor A. Kh. Kūznetzoff's clinic, in Kharkov, undertook a series of observations on twelve patients (*Russkaja Meditzina*, No. 36, 1886, p. 595), to whom he gave a decoction of from $\frac{1}{2}$ to $1\frac{1}{3}$ drachms of quillaia in 6 ounces of water with syrup (as recommended by Kobert). Two of the patients suffered from emphysema pulmonum, one from interstitial pneumonia with bronchiectasis, four from phthisis, one from left pleuro-pneumonia, one from syphilitic stenosis of the right bronchus, and three from croupous pneumonia. The outcome of the author's experiments may be summed up thus: 1. Quillaia does not irritate the gastro-intestinal tract (no vomiting nor diarrhoea ever occurred). 2. It increases the discharge of sputa. 3. It soothes cough. 4. But, in presence of a disposition to hæmoptysis, the drug may give rise to an attack of the latter. Hence it is contraindicated in cases of the kind. 5. In some cases of phthisis it may intensify cough without alleviating expectoration. 6. On the whole, however, quillaia as an expectorant is preferable to senega.—*Medical Record*, January 15, 1887.

INDIAN HEMP IN THE TREATMENT OF CERTAIN TYPES OF HEADACHE.

In the treatment of headache of a dull continuous character attended sometimes by paroxysmal exacerbations, Dr. STEPHEN MACKENZIE has obtained considerable relief through the use of Indian hemp (*British Medical Journal*, January 15, 1887). In this form of headache constancy is its special characteristic. Patients will state that they rise with it in the morning, are troubled with it all day, and carry it to bed with them at night. If by chance they awake in the night they find their head is aching. The headache may in some cases be aggravated as the day advances, but sometimes the opposite condition obtains, and the headache is worse at the early part of the day. It may be frontal, temporal, or occipital, or, more rarely, vertical. Usually, however, it is diffused. It is not as a rule attended with local soreness or tenderness. Nausea may be present, but is not constant;

vomiting is usually absent. In some cases distinct exacerbations, sometimes of great severity, occur. As these subside they give place to the dull continuous headache that preceded their advent. As a rule, the ocular phenomena characteristic of migraine are absent, and the headaches are not usually hemi-craniel. Constipation is present in a certain number of cases, but removal of the constipation does not cure the headache. In some cases it is associated with disorders of digestion, but the same remark applies to these as to constipation.

Headaches of this type may last for weeks, months, or even years. They occur in persons of different ages, but are, perhaps, most common in the middle period of life, and in young adults. Several of the best marked cases which came under the author's notice have been in medical students. Patients so suffering are usually able to pursue their usual avocations, except, perhaps, during paroxysmal exacerbations, especially when their work is of an active rather than of a sedentary and intellectual character. Thus medical students have been able to attend to their dressing and other duties at the hospital, but when they have attempted to read they have found it impossible; the headache prevented the full engagement of their attention.

In the majority of such cases the use of Indian hemp in Dr. Mackenzie's experience will be of the greatest service. In the majority of cases it will cure the complaint. The one element of the headache which in his experience indicates the probable success of the remedy is its continuous character. The preparation which he always employs is extract. He begins by giving one-third or, more usually, half a grain night and morning, or occasionally three times a day. If at the end of the week some amelioration of the headache has been procured, he continues its use in the same doses, but if little or no improvement has taken place, he increases the dose to one grain at night and one-half a grain in the morning; if this is insufficient, the doses should be increased so as to make it one grain night and morning; and this failing, the dose should be gradually increased by half-grains, giving the maximum quantity at night, until two grains at night and one and one-half grains in the morning are reached. It will be seldom necessary, according to Dr. Mackenzie, to exceed this dose. Two points are especially important in order to procure success. The doses should be gradually increased in size, and its employment should be

steadily persevered in. The treatment must be as obstinate as the disease.

Given in these doses, usually no inconvenience is experienced by those taking cannabis indica; but a few patients have complained of a feeling of slight confusion or giddiness, not in any way so annoying as the condition for which it was administered.

The length of time over which treatment has to be continued varies in different cases; usually it extends over several weeks, but rebellious cases may require a treatment of two or three months. As the malady recedes, the dose should be reduced, and it is advisable to continue the administration of the remedy for a week or two after the headache has disappeared.

In the majority of cases the Indian hemp may be given alone, with compound glycerhiza powder, powdered valerian, or extract of gentian, as excipients. It by no means follows, however, that because our patient has a headache we are not to attempt to relieve his other sufferings. Thus, when constipation is present, as it is in a fair number of cases, some aperient may conveniently be combined with the hemp; aloes and myrrh pill, compound rhubarb pill, in small doses, may be added to the cannabis indica. Where flatulence troubles the patient, compound asafœtida pill, carboic acid, or quinine, separately or combined, may be given with the Indian hemp in a pill.

RHIGOLENE AND OIL AS A VEHICLE FOR SPRAYS.

In the *Medical News* for April 16, 1887, DR. AUGUSTUS STABLER calls attention to the fact that the employment of a mixture of rhigolene with one of the expressed oils is free from the irritation possessed by any mixture or combination that has water as a basis, and is more readily worked than the mixtures in which oils are employed. He employs a mixture of two drachms of olive oil or almond oil, and claims that it requires no more pressure than water to be converted into a fine spray. When sprayed into the mouth, the lips being closed upon the tube, and the patient being instructed to inspire quietly through the nose, the spray issues like a cloud from the nostrils. It is thoroughly non-irritating to the most sensitive tissues, and, in fact, appears to act slightly as a local anæsthetic. It does not catch fire when directed over an uncovered lighted gas-jet, and does not produce general anæsthesia. It would, therefore, appear to enable us by its employ-

ment to succeed, by directing the spray in the mouth, in easily applying local medication to the glottis. Dr. Stabler calls attention to the following substances, which are readily soluble in this mixture :

Copaiba balsam, cubebæ ol., camphor, eucalyptol, iodine, iodol, iodoform, menthol (crystals), naphthalene (crystals), phenol (crystals), resorcin, sassafras ol., salol, terebinthinæ ol., thymol.

Resorcin is insoluble in rhigolene, but dissolves in olive oil to the amount of nearly five per cent. The mixture will hold about three per cent. in solution. Every oil thus far tried seems to be readily miscible with the rhigolene and sweet oil, so that the entire list of essential oils and turpentine may, *a priori*, be added to the above list.

He has not found any astringent that will dissolve in olive oil or in the mixture containing it, but *iodo-tannin* may be prepared as follows :

Take a saturated tincture of iodine and dissolve in it as much tannin as it will hold. This will mix with castor oil in any proportion, and the mixture may be thinned with rhigolene to the desired consistence. It makes a very handsome, clear red solution, and though slightly irritating, is not excessively so, and the irritation very rapidly subsides.

Cocaine is insoluble in the olive oil and rhigolene mixture, but like tannin makes a perfect solution if first dissolved in alcohol and then mixed with castor oil and rhigolene.

THE INFLUENCE OF CERTAIN DRUGS ON THE CIRCULATION IN THE BRAIN AND IN THE FOREARM.

CAPELLI and BRUGIA having been so fortunate as to fall in with two cases in which, owing to injury, the skull was wanting to a considerable extent, instituted a series of experiments with a threefold object. They wished to determine (1) the variations that some therapeutic agents bring about in the volume of the brain; (2) the modifications caused in the form of the cerebral pulse by the same means; (3) and finally, to compare the sphygmographic and volumetric tracings of the brain and of the forearm under the action of the drugs.

The method of experimentation was in all respects the same as that adopted by Mosso. The observations were made in a quiet room, and the subject was always put into the same posture. A sober and uniform mode of life

was insisted upon. Before making any fresh observation a tracing of the normal pulse was obtained.

Seven therapeutic agents in all were submitted to examination, namely, nitrite of amyl, morphine, chloral, paraldehyde, hyoscyamine, the cold bath, and the warm bath. The following is a *résumé* of the experiments :

I. *Nitrite of Amyl*.—That this substance produces paralysis and conspicuous diminution of the blood-pressure has already been long known. The proportion, however, in which the different vascular regions are acted upon in this manner has not hitherto been exactly made out. The authors, therefore, have thought it of value to place in comparison the modifications caused by the drug at the same time in the circulation of the brain, in the circulation of the forearm, and in the impulse of the heart. From the tracings obtained it appears (1) that the vapor of amyl nitrite diminishes the strength of the heart's beat; (2) that the action of the drug is much more rapid and more evident in the vessels of the brain than in those of the forearm; and (3) during the inhalation marked oscillations in the volume of the forearm and of the brain take place. The undulations in the tracings due to this cause are not isochronous, and probably depend therefore on pulse changes of local origin.

II. *Morphine (Hydrochlorate)*.—This drug was given hypodermically, in doses of 1 to 2 centigrammes. Three periods were observed in its action.

1. During the first period, which lasts a few minutes after the administration of the medicament, there is a small degree of constriction, both in the arteries of the forearm and of the head. This is shown by the approach of the curves to the abscissa, diminution of the influence of respiration on them, less height of the individual pulsations, and a better marking of the elevations of elasticity.

2. The period of constriction is followed by a diminution of the vascular tone, which reaches its maximum when sleep has already begun to show itself. There is, therefore, a contemporaneous increase in the size of the forearm and of the endocranial pressure.

3. In the third period the vascular tone is gradually regained while sleep still continues, marked oscillations, however, occurring at intervals.

III. *Chloral*.—The experiments of the authors led to conclusions which differed in part from those of Curci, who holds that during chloral sleep there is diminution of

the cerebral mass through lessened afflux of blood. Drs. Capelli and Brugia consider that chloral has a paralyzing action on the vessels,—earlier and more manifest on the peripheral arteries than on those of the brain. Hence they divide the effects of the drug into two distinct periods.

1. There is, first, a period of cerebral anæmia due to the diminished arterial resistance at the periphery. This continues until the commencement of sleep.

2. Then comes a time when the cerebral vessels become paralyzed, and the volume of the brain increases. This increase lasts for a variable time, and is afterwards followed by a second period of anæmia, which coincides with waking, and is continued into the subsequent period of the waking state.

IV. *Paraldehyde*.—Paraldehyde has not always the quick and certain hypnotic action that was at first hoped for it; and the authors have tried to find whether any difference in its vascular action was traceable, according as the drug answered its purpose or not. The dose employed was always 3 grammes.

1. A few minutes after taking the medicine the force of the cardiac beat diminishes; and this diminution goes on steadily till it reaches its maximum during the most profound sleep. This effect is much less evident in those cases where the remedy fails to have an hypnotic influence.

2. In about ten minutes the pulse at the wrist begins to be modified. The apex becomes rounded, and the elevations of elasticity disappear almost altogether. The volume of the forearm at first undergoes a slight diminution, due, perhaps, to the lesser cardiac force; then it gradually increases as the vascular paralysis becomes more marked.

3. In the cerebral circulation the effect is very slight, apart from the general action on the blood-pressure. From all this it follows that if paraldehyde were a certain hypnotic, it might with advantage be employed instead of chloral to avoid the vascular paralysis produced by this latter drug. Nevertheless, it must not be forgotten that paraldehyde is not itself innocuous, especially when given in large doses. Its rapidly depressing effect on the heart is a contraindication in subjects where this organ is weak.

V. *Hyoscyamine*.—The following are the results of hyoscyamine administered subcutaneously in doses of 3 milligrammes:

1. A few minutes after the administration of the alkaloid the cardiac energy and the vascular tone increase.

2. Twenty minutes later the force of the heart's action diminishes, the tone of the vessels falling at the same time. At this time one notices a considerable increase in the frequency of the pulse and a diminution—not constant, however—in the volume of the forearm and of the brain.

3. With the higher degree of narcotism coincides the greater frequency of the pulse, the lessened cardiac energy, and the lower degree of vascular tone. The normal condition is regained in a gradual and intermittent manner, so that both the forearm and the brain undergo alternate increase and diminution in volume.

VI. *The Cold Bath*.—The general cold bath (15° C.,—i.e., nearly 59° F.) gave the following results:

1. The volume of the forearm underwent an immediate and well-marked diminution. The form of the individual pulsations was no longer recognizable, being masked by the fibrillary contractions of the muscles of the limb. After twenty-five or thirty minutes the oscillations of elasticity again became evident.

2. In the brain a steady and progressive increase of volume is observed. The outline of each pulsation decreases considerably at first, but after half an hour exceeds the normal tracing in height.

3. The frequency of the pulse, at first increased, afterwards undergoes a slight diminution.

VII. *The Warm Bath*.—The authors, in their experiments on the warm bath, repeated several times, have not verified either the diminution of the tonic of the cerebral vessels noted by Bergesio and Mosso as a persistent effect of this hydrotherapeutic agent, nor that brief initial period of three or four minutes in which, according to them, there is rapid congestion, chiefly venous, of the brain. From the tracings taken by the authors, it results, on the contrary, that during the whole period of the warm bath there is a slight degree of constriction of the cerebral vessels, which sometimes takes place immediately on getting into the bath, sometimes a few minutes later. The volume of the brain was, as a rule, diminished from the first moment; sometimes, however, there was a slight rise at the commencement. In any case, after a few minutes, a manifest and persistent anæmia was established. This result is in agreement with the observations of Bergesio and Mosso. In every case the tracings of the forearm gave evidence during the entire duration of the experiment of diminished vascular tone and of

increased size of the limb. This condition commenced from the moment of immersion.—*London Med. Record*, January 17, 1887.

THE PHYSIOLOGICAL AND THERAPEUTIC ACTION OF URETHAN.

DR. A. P. LANGOVOL, of Moscow, gives (*Vratch*, No. 7, 1887, p. 179) the following summary of the results of his own experiments on the physiological and therapeutic effect of urethan: 1. The hypnotic effect of urethan manifests itself in different kinds of animals in different degrees. Thus, it produced a powerful effect on rabbits, while it acted very slightly on dogs. 2. Even large doses of urethan had not any marked poisonous effect on the heart, nor did they depress the arterial tension. 3. Breathing is quickened by urethan. 4. The drug is well borne by patients, has not a disagreeable taste, and does not cause any gastric disturbance. 5. Given in ordinary medicinal doses, urethan does not produce any unpleasant secondary effects, such as failure of the cardiac action, etc. 6. Its chief effect is on the brain; it does not seem to act on the peripheral nervous system. At all events, in cases of sleeplessness from cough or pains, it has no marked effect. 7. Urethan is not a powerful hypnotic, and in certain cases it is inactive or nearly so. Nevertheless, as it has no tendency to produce any untoward secondary effects, it may be regarded as a faintly useful addition to our therapeutical resources. It is a useful hypnotic in nervous insomnia, as well as in sleeplessness in the course of acute fevers.—*The British Medical Journal*, March 19, 1887.

ACUTE EPIGASTRIC PAIN IN PUERPERAL ALBUMINURIA.

In the *Lancet* for April 2, 1887, Mr. JOHN PHILLIPS calls attention to an important but apparently neglected premonitory symptom which sometimes occurs in cases of albuminuria in pregnancy. While cephalalgia and derangement of vision are recognized as precursors of puerperal eclampsia, Mr. Phillips refers to five cases in which the albuminuric pregnant women were suddenly attacked with an epigastric pain. Although these instances are so few in number as to perhaps be insufficient to substantiate the conclusions Mr. Phillips would draw from them, they indicate the reality of such a symptom occasionally existing and the necessity for prompt

treatment. The pain passes from the epigastrium to the back of the lower chest; it may be variable in degree, but is usually agonizing in character. Pressure and vomiting appear to relieve it somewhat. It is paroxysmal, and, although usually occurring ante-partum, may, as in one case detailed, arise afterwards. Convulsions may or may not follow its advent. The pain appears to arise from some perversion of nutrition of the solar plexus; probably the circulation of vitiated blood in its substance may be the primary factor. Another point in favor of its nervous origin is that three out of the five patients suffered severely from neuralgia in other parts of the body.

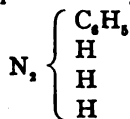

"AMYKOS" IN CATARRH AND GONORRHOEA.

In the *Russkaia Meditsine*, No. 46, 1886, p. 793, DR. J. J. TRUSEWICZ, of St. Petersburg, draws attention to "amykos," an antiseptic fluid prepared in Upsala and extensively used all over Sweden and Finland. Its essential constituents seem to be boracic acid and thymol. Diluted with two or three volumes of water, amykos makes a good injection or irrigation in acute and subacute coryza and syphilitic rhinitis. The author also found solutions of amykos very useful as collyria in acute conjunctivitis and as irrigations in catarrhal otitis. The best results, however, were obtained in acute and chronic gonorrhœa; the burning pain on micturition was immediately relieved, and after two or three days the discharge became mucous instead of purulent. It is well to begin with weak injections (one part of amykos to four parts of water). After two or three days the strength of the solution may be gradually increased. In mild cases the disease was cured in about a week. When the mucous discharge does not cease about that time, some astringent, such as sulphate of zinc or acetate of lead, should be added to the amykos solution.—*The British Medical Journal*, March 19, 1887.

ANTITHERMIN.

"Antithermin" is the name that has been proposed for a new synthetically-prepared compound which has just been added to the army of antipyretics (*Nouv. Remèdes*, March, p. 102). The systematic name of the compound is "phenylhydrazinlevulinic acid," from which it is evident that it has a near chemical relationship with "antipyrin." It will be re-

membered that one of the intermediate products in the formation of this widely-used antipyretic is phenylhydrazin, the composition of which is represented by the formula

This compound has the property of combining with other compounds to a remarkable extent, as, for instance, with aldehydes, ketones, sugars, and ketone acids, antipyrin being, in fact, a methylated derivative from a compound of phenylhydrazin with acetoacetic acid. The new antipyretic is a compound of phenylhydrazin with acetopropionic acid, a homologue of acetoacetic acid, to which the name levulinic acid also has been applied, because it can be prepared by oxidizing levulose. Phenylhydrazinlevulinic acid, or antithermin, is said to be obtained by dissolving phenylhydrazin in dilute acetic acid, and adding to it a solution of levulinic acid, which gives rise to a yellow precipitate that yields well-formed crystals upon recrystallization from alcohol.—*Pharmaceutical Journal and Transactions*, April 2, 1887.

THE MECHANISM OF THE THIRD STAGE OF LABOR.

At the meeting of the Obstetrical Society of London, held April 6, 1887, DR. CHAMPNEYS (*British Medical Journal*, April 16, 1887) read the continuation of his paper with the above title, the first part of which has been already brought before the readers of the GAZETTE.

The author in this contribution deals with "the Expulsion of the Placenta." The author reviewed the literature of the subject, including the observations of Lemser, Salin, Duncan, Schultze, Ribemont, and Ahlfeld. He then gave his own observations of 70 cases, carefully observed and tabulated, as regards the manner of the expulsion of the placenta and the blood-loss in each case; the measures of the membranes and presenting-point of the placenta were given in the table. The foetal surface presented in 64, the maternal in 2 (in both of which the cord had probably been pulled upon), the amnion in 4. Adding his results to those of Pinard and Ribemont, Dr. Champneys found that the foetal surface presented in 127, the foetal edge in 27, the maternal surface in 5. The presenting-point was nearer the lower edge of the placenta in 65, nearer the upper edge in

1, midway in 2, no note of its position in 2. The lower edge, or amnion below the lower edge, presented in 16. In the great majority of cases a point within two inches of the edge presented, but on the foetal surface. There was a complete absence of fundal attachments. It was found that the presenting part varied in its position with the position of the placenta. The higher the placenta the higher the presenting-point, and *vice versa*. The average loss of blood before the expulsion of the placenta was six ounces, in the membranes or with the placenta six ounces, making an average of twelve ounces for each labor, not including *post-partum* hemorrhages. Hence a moderate loss of blood was a normal phenomenon of the third stage of labor. Dr. Champneys's final conclusions were—1. That some measurable hemorrhage was a normal constituent of the phenomenon of the third stage of labor; 2. The placenta presented in the great majority of cases by a point on the amniotic surface; 3. The presenting-point was almost invariably near the lower edge of the placenta; 4. The position of the presenting-point varied with the position of the placenta; 5. The "inversion" of the placenta was not due in the great majority of cases to traction on the cord, but was part of the natural mechanism. These observations, therefore, accorded in essentials with those of Schultze, though his diagrams were greatly exaggerated. These observations bore on the opinion previously expressed as to the causes and mode of separation of the placenta. Therefore (1) it was probable that, in addition to reduction of the placental site, some escape of blood played a part in the ordinary mechanism of placental detachment; (2) the slight inversion of the placenta which did take place was probably due to this cause; (3) the effusion of blood was not, in ordinary cases, sufficient to form a large mass bulging into a large uterine cavity behind the placenta.

DR. MATTHEWS DUNCAN congratulated the society on the elaborate papers just read, not only on account of their intrinsic value, but also because of their bringing the society into contributing to the progress of the greatest obstetric work of the century. In the history of midwifery there were only three works of the very highest class as yet achieved. The first in scientific order of progress was done in the eighteenth century by W. Hunter, whose plates of the anatomy of pregnancy were its crown. The second was a work mainly of this century, and was known as the mechanism of parturition, and with it were

connected many names, especially those of Solayrer and of Nægele. The third was still incomplete,—the greatest, most difficult, and most glorious of all, a work of the nineteenth century, the anatomy of labor. In this country no name was so great in the anatomy of labor as Barbour, and he was actively engaged in it at this moment. No contribution to it had come from London, and the papers of Dr. Champneys he hailed as worthily bringing a part of it before this society. The anatomy of labor made no progress till the introduction of complete sections of frozen bodies. No such sections had been done in London, and nowhere had such sections been made in the third stage of labor. The work of Dr. Champneys was mainly physiological, and should come after the completion of the anatomy of the third stage, for the subject of his work would not be settled till the anatomy was finished. Failing to find bodies for the sectional anatomy of the third stage, obstetricians had examined the uteri of the operation of Porro. This was an imperfect substitute for frozen sections, and might be very misleading. The Porro uterus examined by Barbour showed that the placental area might be contracted to a diameter of four inches without separation, and the absence in these cases of hæmatoma was hostile to the theory of separation by utero-placental hemorrhage, but it did not disprove it. Absence of separation with contraction to an area of four inches in diameter seemed to astonish many and to favor the detrusion theory of separation. Dr. M. Duncan always imagined a much greater contraction as necessary for separation. He referred to his own paper of 1871, which was now a matter of "ancient history," and would not be praiseworthy at this date; yet, admitting its imperfections, he was still an unbeliever in the presence of hæmatoma in a natural separation in a theoretically natural case, and he continued to hold that the cake descended edgewise through the cervix, and referring to Dr. Champneys's table, columns A and B, confirmed this. The old detrusion theory of separation he had found difficult to make intelligible. He could not understand the production of detrusion till after separation. He could not imagine detrusion pushing off the lowest flap (as in the Porro case exhibited by Dr. Galabin) without pushing off all above it.

DR. GALABIN understood that the author had not come to a decided opinion whether the separation of the placenta was from the periphery to the centre, or *vice versa*. Dr.

Galabin thought this depended on the cause of separation. If the cause were from shrinking of the placental site, separation must be from the periphery inwards. If hemorrhage were the cause, it must occur away from the margin, and could only effect a separation from the centre towards the periphery. Even if it were admitted that an effusion of blood was normally present, it did not follow that the hemorrhage was a cause rather than a consequence of detachment. Dr. Galabin thought that the Porro uterus was in favor of shrinking of the placental site, with possibly detrusion as a cause of detachment, and not hemorrhage. Detrusion, acting as a supplementary cause of shrinking, would cause detachment of the lower margin first. As regards the mechanism of expulsion, he thought it depended on the management of the third stage of labor. In Salin's cases, the placenta presented at the os by its lower margin, and there was no inversion. In Champneys's cases there was partial inversion. In Lemser's cases, the upper edge usually presented. The probable reason was that the management of Salin's cases promoted the best uterine contraction; that of Lemser's the greatest relaxation; that of Champneys an intermediate condition. Dr. Galabin did not think that leaving the uterus unsupported, with the patient on her side and the fundus dependent, would give the most ideally natural mechanism.

DR. HANDFIELD JONES thought that an ideally healthy labor was bloodless as regards the separation of the placenta, though variable amounts might flow afterwards.

DR. BOXALL thought there were causes for separation of the placenta not mentioned in Dr. Champneys's papers. After the birth of the child, the conditions were profoundly altered, the flow of blood from the foetal portion of the placenta to the lungs ceasing, the thin lamina of maternal tissue is deprived of support towards the cavity of the uterus. The position in which the placenta is implanted on the uterus Dr. Champneys had shown to be important, and this again is indissolubly connected with the separation of the membranes. As long as the membranes at the edge of the placenta remained adherent to the uterine wall, inversion of the placenta was maintained. If any portion of the attachment gave way, the adjacent margin of placenta, being no longer supported, became the most dependent part, and the sub-placental hæmatoma found an exit of escape, and the lower the implantation of the placenta, the

more easily would this happen. There were other causes that altered the process of detachment, as pulling on the cord and abnormal adhesion. Dr. Boxall explained a series of experiments which he had made to determine the placental presentation by means of staining. He also confirmed Dr. Champneys's remarks on the rarity of fundal attachment of the placenta. He had found the fundus overlapped (to the extent of an inch and three-quarters) only once. Out of 100 cases, he should say that the placenta would occupy the upper zone in 21 cases, the middle zone in 77, and the lower zone in 2.

"MASSAGE" FOR THE TREATMENT OF CORNEAL OPACITIES.

There are, perhaps, no affections of the eye which cause more disappointment to both surgeon and patient than the opacities of the cornea which are left by keratitis and ulceration. After prolonged and varied treatment, the inflammation, which has perhaps undergone many remissions and relapses, finally subsides, only to leave an eye which is practically useless, owing to the loss of transparency of a great part of the cornea. So many different modes of treatment have been suggested for this condition, and, after trial, have been abandoned as useless, that there is much natural scepticism as to the efficacy of any new proceeding, and most surgeons trust to the effect of time and Pagenstecher's ointment. In a paper read before the British Medical Association at Brighton, MR. SNELL redirected attention to friction or "massage" as a mode of hastening the disappearance of corneal opacities. Although not capable of effecting all that was at one time claimed for it, it has now stood the test of time, and may fairly be said to have met with more success than any other single mode of treatment. First proposed by Pagenstecher, in 1872, as a means of hastening the absorption of corneal opacities, it has since been advocated by many writers. But Dantziger (*Archiv für Ophthalm.*, xxxi. 3, 187) has shown that its sphere of usefulness can be considerably enlarged, if it be preceded by the mechanical removal of the opaque corneal tissue by scraping. The employment of "massage" during cicatrization then prevents the newly-deposited tissue becoming opaque. Although there is some difference of opinion on points of detail, the following is probably the best mode of employing the "massage." The inner surface of the eyelid should be lubri-

cated, preferably with Pagenstecher's ointment; the pulp of the finger is then laid on the lid, and the latter moved to and fro over the cornea with great rapidity, in a direction radiating from the centre of the cornea. The operation is continued for about a minute, and repeated daily, as long as improvement continues to take place. The results of Dantziger's cases would encourage us to persevere for a considerable time. In a patient in whom a corneal opacity had existed for four years, and in whom vision was reduced to the counting of fingers at six feet, gradual improvement continued to take place during the whole five months during which the "massage" was continued: vision being fingers, at 15 feet after two weeks; 12 J. after twelve weeks; and $\frac{20}{200}$ and 8 J. at 5 inches after five months. No doubt the necessity for continuing the treatment for so long a time has hindered its adoption; but an intelligent patient can easily be taught to perform the "massage" for himself. The preliminary removal of the corneal opacity would seem best adapted for cases of dense opacities affecting a limited area. Cocaine produces sufficient anæsthesia, the reaction is considerable, and usually lasts till the fifth or eighth day. The "massage" may be commenced as soon as the epithelium has been re-formed, the presence of vessels on the cornea not being considered a contraindication. Some cases seem to be unsuited for this treatment, and suffer after the "massage" from prolonged injection of the conjunctiva; but cases of old opacity, in which all the inflammatory symptoms have long subsided, appear to be more benefited by it than by any other mode of treatment.—*The Lancet*, April 2, 1887.

ACETYL-AMIDOPHENOL.

Still another antipyretic that is threatened to invade us from Germany is described variously as being p-acetphenetidin (*Cent. f. Med. Wissen.*, 1887, No. 9) and p-acetphenidin, or acetylated p-amidophenol, $\text{NH}_2\text{C}_6\text{H}_4\text{OCH}_3\text{CO}_2\text{H}$ (*Pharm. Centralh.*, March 17, p. 143). A writer in the *Pharmaceutische Zeitung* (March 26, p. 178) points out that this leaves the identity of the compound still in doubt, for not only is the formula given inconsistent with either name, but that para-amidophenol is theoretically capable of yielding two acetyl derivatives, an acetyl residue replacing hydrogen in the NH_2 group in one and in the HO group in the other. Probably, however, as the compound is the subject of a patent, this

is of little practical importance. The compound is said to occur in small colorless or faintly reddish needles, which are tasteless, difficultly soluble in water, but somewhat more freely soluble in alcohol and strong acetic acid, and melt at 135° C. The preparation is given in doses of 0.2 to 0.5 gramme; but according to Messrs. Hinsberg and Kast, who have experimented with it, doses of 1 to 2 grammes have proved harmless. Up to the present time this new antipyretic does not appear to have been favored with a trivial name; but should it come into sufficient use to make one desirable, it may be hoped that an effort will be made to get outside the monotony of "anti," which now threatens to become a source of confusion.—*Pharmaceutical Journal and Transactions*, April 2, 1887.

THE TREATMENT OF SYPHILIS.

At a recent discussion at the Medical Society of London on a paper read by MR. MILNER, divergent opinions with regard to the treatment of syphilis were expressed, and some valuable and interesting remarks were made by DR. LAUDER BRUNTON and DR. ALTHAUS. The effect of mercury in controlling to some extent the secondary manifestations of syphilis is assumed to be due to its properties as a germicide, and the same convenient explanation is given of the undoubtedly beneficial action of iodide of potassium in the later stages. It was pointed out, however, that the effects of iodide of potassium or sodium are due, not to the iodine, but to the salt, which is not a germicide. Further, it was remarked by several speakers that the action of the iodides, while prompt and certain in dissipating the local symptoms which are supposed to belong to the later stages of syphilis, is not permanent. It has, indeed, been generally recognized that the iodides of potassium and sodium are only indicated in the lesions which occur in various tissues from the action of the virus in the past. Dr. Brunton appeared disposed to allow that mercury might owe its effect in syphilis to its action as a germicide, and observed that whatever its influence on the diseased germ, it was detrimental to the tissues. Further, there was a very general expression of opinion that iodide of potassium, like mercury, was not a drug to be trifled with; and the propriety of employing mercury, even in the later stages, found several supporters. Inunction as a method of treatment has become more systematic of

late years, especially since pharmaceutical research has placed at our disposal more elegant and convenient preparations for the purpose.

Dr. Althaus spoke very highly of the oleate of mercury as a cleanly and readily-absorbed preparation, and the peculiar qualities of lanolin as a vehicle for the administration of drugs, and particularly mercury, by the skin, also elicited expressions of approval. For severe cases the intra-muscular injection of mercury in some form or another, as practised by Mr. J. Astley Bloxam at the Lock Hospital, is productive of good results, though patients are apt to resent the pain which accompanies its introduction. Each method of mercurial administration possesses certain advantages. A clear and well-defined classification of the indications for each method is still wanting, though Dr. Milner has filled the gap to some extent in the paper referred to.—*British Medical Journal*, March 12, 1887.

GLANDULAR SWELLING CURABLE BY ARSENIC.

At a meeting of the Clinical Society of London, held March 25, 1887, MR. FREDERICK TREVES (*Lancet*, April 2, 1887) read a paper on "A Form of Glandular Swelling which is Cured by Arsenic." He drew attention to the obscurity that attends both the pathology and the clinical history of certain chronic glandular affections. These affections are covered by such terms as the following: hypertrophy of glands symptoms, malignant lymphoma, lymphadenoma, Hodgkin's disease, and lymphosarcoma. These glandular swellings are considered to be un-inflammatory, have no relation to scrofula or syphilis, and are clearly separated from the gland disorders that attend leucæmia. They possess the common characters of a slow origin without apparent cause, a slow but progressive growth, and an absence of all inflammatory phenomena. Histologically there would appear to be no means of distinguishing one of these affections from another. Apart from this, objection may well be raised to the terms hypertrophy and lymphoma. Without limiting himself to any special term, Mr. Treves desired to draw attention to the clinical aspects of a certain form of non-leucæmic gland-enlargement that could be cured by arsenic. The patients are usually past middle age; they present no peculiar constitutional defect; there is no suggestion of gout, rheumatism, or scrofula. There is no leucæmia.

The neck is usually involved. The gland-tumors appear on both sides without disturbances in the periphery. The masses vary in size from a hazel-nut to a duck's egg. They are soft, elastic, homogeneous, movable, painless, and free from tenderness. They show a disposition to spread without limit. The temperature is normal, and suppuration does not take place. Mr. Treves gave instances of the cure of such cases by the use of arsenic. The drug is given in the form of liq. arsenicalis, commencing with a dose of 5 minims, and increasing to 20 minims three times a day. The treatment has to be kept up for some months, one to six. The glands waste, some few suppurate, and in such instances the resulting sinuses heal without further treatment. In cases where the whole neck has been filled with great glandular masses the tumors have wholly disappeared after a treatment of from four to six months. Some of these cases, at least, would probably be covered by the term Hodgkin's disease. Mr. Treves concluded by an allusion to Dr. Köbel's paper on the treatment of malignant growth by arsenic administered by the mouth, and also hypodermically.

MENTHOL.

LANGAARD writes as follows in the *Therapeutische Monatshefte* for March, 1887 :

Although menthol was known to chemists for years it was only recently brought to the notice of medical men by Macdonald, and its antiseptic and analgesic properties known : it has been used chiefly in the form of "head-ache" or "migraine" pencils. Experiments to show its adaptability to internal use have been comparatively neglected by physicians, and yet it is true that menthol has a distinct and considerable value which makes it appropriate, if not as a specific, still as an agent of very considerable power in subduing certain symptoms of disease. The neglect to use menthol extensively has doubtless arisen from the lack of literature calling attention to its merits ; the recent experiments of Rosenberg in the treatment of phthisis by menthol make it appropriate to summarize our knowledge of this drug.

Menthol, also called peppermint camphor, is the stearopten of the ethereal oil of peppermint. By cooling to the freezing-point menthol separates in crystals, which are freed from the superfluous oil and are cleansed by distillation. The quantity of menthol contained in German and English samples is so small that the preparations have little value.

American, and above all Chinese and Japanese, samples are most rich in menthol. The two last furnish often pure menthol, containing but little oil, crystalline at ordinary temperatures, and were formerly known to chemists as *oleum menthol Japonicum crystallisatum*.

The great difference in the amount of oil in the different samples of menthol is owing to the differing descent and species of different plants of the mint family. Very different accounts are given of the plant from which are derived the Chinese and Japanese oils. Holmes, who believes that it is possible to distinguish between them, has recently designated the Chinese as *Mentha arvensis* L., var. *glabrata*, and the Japanese as *Mentha arvensis* L., var. *piperascens*. Formerly menthol was an article little used and expensive, but owing to its recent extensive use its price has become much less.

Menthol appears in colorless, shining, needle-shaped or column-shaped crystals, having a strong odor of peppermint and a peculiar cool, aromatic, bitter taste, burning slightly in the mouth. It boils at 212° C., melts at 43° C., and is but little soluble in water, but gives to water its odor and taste. Spirits of wine, ether, and chloroform dissolve it freely ; it is also soluble in oils, fats, and glycerin. When placed over a water-bath it melts to a colorless clear fluid, and should be entirely without sediment of paraffin, wax, or magnesium sulphate : it should be also clear in alcohol, and dissolve without sediment. In a mixture of one cubic centimetre acetic acid with three drops sulphuric acid and one drop nitric acid menthol should remain colorless ; a muddy discolored solution results when thymol is added. The formula of menthol is $C_{10}H_{20}O$: its chemical composition is unknown. Menschutkin believes that it belongs to the series of secondary alcohols. Fischer considers it not impossible that menthol is a "reproductive product" of Borneo camphor, namely, the common Japanese camphor.

Although peppermint and its ethereal oil had been used since very early times by internal administration as an analgesic and antispasmodic in cardialgias, colic, and spasmodic pain by physicians and also the people, the external use of the active principle of this plant to relieve neuralgias, which was formerly common, had fallen entirely into obscurity. Pliny mentions its use in headaches ; the Chinese and Japanese have employed oil of peppermint and menthol from very ancient times as an analgesic, especially successful in nervous and rheumatic head-

aches and in the pains caused by carious teeth. Wright, who had learned the use of menthol in China, reported its good effects in the *Lancet* in 1870. Delieux de Savignac wrote also at this time regarding it.

Under the name of "Po-ho," or "Japanese drops," put up in small flasks, whose labels were in Chinese characters, menthol found common use as a cure for headache.

Macdonald was the first to use pure menthol and report its effects. When menthol, in the form of "migraine pencils," in alcoholic solutions or in ointments, is applied to the unbroken skin, there follows at first a feeling of coolness in the spot where was the menthol, which endures ten or fifteen minutes, and is succeeded by a slightly burning sensation. Neuralgic pains in the region so treated ceased in a few moments, returning perhaps in a quarter of an hour. The working was most pronounced in neuralgia of the head and face, although Law has reported good results in the treatment of intercostal neuralgia by menthol.

Neuralgias situated more deeply are not affected by such applications, although gouty and rheumatic pains are thought to be improved. The favorable results obtained by Macdonald have been repeated by others, and these successes, generally transient, have brought the "pencils" into common use.

The sensation of coolness which follows the application of menthol has given rise to the attempt to produce a similar general effect by a more extensive evaporation of the drug. The investigations of Goldscheider have proved that menthol has a direct influence upon the peripheral nerve-endings. He has also brought forward the interesting fact that the sensation of cold by delayed evaporation is found only in certain localities in the body; that in other portions of the body, as on the flexor side of the forearm, a sensation of warmth, instead of coolness, follows the application of menthol.

Russel has directed attention to the antiphlogistic properties of menthol. Pain, itching, heat, and swelling are greatly lessened after its local use. This point has not been, as yet, fully elucidated. Should menthol be proved of value as an antiphlogistic, a wide field of usefulness would be opened to it. In itching exanthemata and painful hemorrhoids its use may be greatly extended.

Menthol is most commonly used in the form of pencils; its solutions or ointments, although possibly not so convenient, are probably more lasting in their effects.

Macdonald used a ten per cent. alcoholic solution. Steward used a solution in bromethyl. The following is a formula for a useful ointment:

R Mentholi, 1 part;
Ol. olivari, $\frac{1}{2}$ part;
Lanolini, $8\frac{1}{2}$ parts. M.
F. unguentum.

Sig.—Lanolin migraine ointment.

For many uses, as applications to the mucous membranes, the following formula, which gives a semifluid product, is useful; the substance resulting may be conveniently applied by a camel's-hair pencil:

R Mentholi, 1 part;
Dissolve in
Ol. olivari, 3 parts, and add
Lanolini, 6 parts. M.
F. unguentum.

In the treatment of burns the following lotion may be used in place of ointments:

R Mentholi, 1 part;
Dissolve in
Ol. olivari, 9 parts, and add
Aq. calcis, 10 parts. M.
F. linimentum.

Menthol may also be used in combination in plasters, and has in this form manifold applications.

For toothache from caries a small crystal of menthol may be placed in the hollow tooth, or a mixture of equal parts menthol and chloral hydrate. As is the case when camphor and chloral are mixed, a fluid results. A pledget of cotton may be saturated with menthol chloral and placed in the hollow of the tooth.

Rabon recommends menthol as snuff in the treatment of coryza. The effect of menthol as a local anæsthetic is much weaker than its analgesic effect. The proposal of Rosenberg to combine menthol with cocaine for the production of local anæsthesia in the nose and pharynx cannot be considered of great value. In the treatment of reflex neuroses, whose origin was the nasal cavity, Rosenberg obtained excellent results with small bougies of glycerin and gelatin which contained one-sixth grain of menthol; these were inserted into the site of the lesion.

In ophthalmology menthol cannot be used as an addition to cocaine. Schmitz witnessed marked symptoms of great irritation, painful, burning sensations, photophobia, hypersecretion of tears and conjunctival injection per-

sisting for several hours after its instillation into an eye.

In addition to its antineuralgic effects MacDonald found that menthol in one-tenth per cent. alcoholic solution was as potent in hindering the development of bacteria as a solution of carbolic acid two-tenths per cent. The writer (Langaard) made investigations regarding the antiseptic effect of menthol in Japan in 1878. The results were so unsatisfactory that no attempt was made to use menthol in wounds: the great quantity of fluid required in its application, its slight solubility in water, and the inconvenience of the use of oily solutions render menthol of little value for this purpose. It is not impossible, however, that its peculiar properties may render it of value in the treatment of infectious diseases.

Cutter observed the happiest results from menthol inhalations in epidemic influenza.

Salisbury treated a case of diphtheria with hourly doses of $\frac{1}{10}$ of a grain; complete recovery followed in twenty-four hours.

Inhalations of menthol would be indicated in diphtheria in addition to its internal use.

Rosenberg's use of menthol in phthisis is based upon its antiseptic properties.

The good effects of preparations of peppermint in many forms of stomach and intestinal catarrh are well known. Menthol is indicated in abnormalities in the solution and decomposition of food in the stomach and intestines.

Koch found that oil of peppermint destroyed cholera bacilli in solutions of 1 to 2000. The internal administration of considerable doses of menthol, combined with enemata of menthol-water, should be tried in cholera. We possess in menthol a remedy which is not dangerous when given in large doses, and which in its dilute forms exercises an energetic influence in destroying the lower organisms. In its internal use its analgesic and anæsthetic properties are valuable in cardialgia, colic, and to check emesis.

Its use is contraindicated in threatened ulcer ventriculi. The first careful observations regarding the more remote effects of menthol were made by Pellacani. He found it to be a paralyzant of the cerebro-spinal nervous system, obtunding, and in large doses destroying, sensation and reflex sensibility, increasing the respiratory rate and lessening the depth of the respirations.

Menthol stimulates the heart-muscle; it does not affect the frequency of the pulse, but, like camphor, it produces periodic increase in arterial tension.

It is indicated as an antispasmodic, to lessen reflex irritability and as a sedative.

We know little regarding the influence of menthol upon the secretions. Schmitz asserts that it stimulates the secretory nerves, and is therefore indicated in stomach and intestinal troubles with deranged digestion; in chronic pulmonary catarrh with tenacious secretions and scanty sputa.

Delieux de Savignac, whose observations were made with oil of peppermint, reports a diminution in the secretions of the mucous membranes, but an increase in perspiration and secretion of urine: a portion of the menthol taken is eliminated by the kidneys as menthol-glykuriic acid.

Regarding the influence of menthol upon the temperature we know nothing; according to Markuson, inhalations of oil of peppermint produce a fall of temperature. For the internal use of menthol pill form should be chosen, as follows:

R Mentholi, gr. xxx;
Sacchar. albi,
Gummi arab., aa gr. xv;
Aq. dest., q.s.
Ut f. pil. No. xx. Obduc. gelatina.

To make a pill which shall retain the properties of the drug, the menthol should be mixed with sugar, moistened with spirit, and the mass thoroughly rubbed until the alcohol has evaporated. The gum may then be added, and after, by thorough rubbing, a homogeneous mass has been made, it may be made into pills on the addition of a little water; a few drops only are commonly needed. Each pill contains one and one-half grains. In this form large quantities of the drug may be given without burdening the patient.

POISONING BY BISMUTH USED AS A SURGICAL DRESSING.

According to the Paris correspondent of the *British Medical Journal*, April 2, 1887, M. P. DALCHÉ recently brought a case of poisoning by subnitrate of bismuth dressings under the notice of the Société de Médecine Légale de France. A woman, aged 30, was under the care of M. Peyrot for two burns. One of these was of the third degree, and extended from the lower angle of the shoulder-blade to the gluteal region, occupying the entire width of the back. The other was a large burn on the left arm. On September 26 these wounds were dressed with subnitrate of bismuth. The dressing, though changed every

second day, became very offensive. The general condition of the patient had been improving; but on October 11 the throat became sore, and she complained of dysphagia. False membranes of a white color were seen on the palate, the uvula, and the tonsils. On October 13 the patches had spread; the mucous membrane round them was black; and the edge of the gums of the lower jaw was rough, and dark brown in color. There was also a patch of false membrane on a base of blackened mucous membrane on the lower lip. The general condition was, however, still good, and there was no albumen in the urine. A few days later the breath became offensive, and there was gangrene of the palate. On the 26th the patches above described had partly disappeared, but there was a burning sensation under the tongue. There was violent diarrhoea and continual vomiting. Some patches of false membrane on the buccal surface of the cheeks had a rough black edge. The bismuth dressing was then given up. Up to November 1, vomiting, diarrhoea, and hiccough persisted, and there was albumen in the urine. On November 5 there was pain along the œsophagus. Several of the patient's teeth became loose. In spite of this she continued to improve, and recovery was complete by the middle of December. M. Dalché is convinced that the bismuth dressings were the cause of the lesions observed, which were not the lesions characteristic of diphtheria, nor of any known form of stomatitis. The bismuth was pure; it was present both in the fæces and in the urine.

PHYSIOLOGICAL ACTION OF NITROUS OXIDE GAS.

DR. DUDLEY BUXTON has communicated two valuable papers upon the above subject to the Odontological Society, based upon numerous clinical observations and experiments. The effects of nitrous oxide inhalation upon the mammalian organisms are, he says, broadly speaking,—(1) a condition of anæsthesia; (2) an emotional state, provoking a sensation of exhilaration,—in fact, it plays the rôle of a stimulant; (3) it gives rise to modifications of the respiratory and (4) circulatory systems; and (5) provokes marked muscular movements, which may be classed as (a) rigidity and (b) jactitations. The anæsthesia produced by nitrous oxide is not dependent upon analgesia or loss of sensation of painful impressions of the sensory end-

organs, such as that produced by cocaine, etc., or upon failure of the conducting sensory nerves, for sensation is retained until the perceptive powers themselves cease to receive; moreover, there is immediately anterior to the loss of consciousness a hyperæsthetic stage, therefore it may be concluded that the nerve-centres are acted upon. The ways by which nitrous oxide may enter the system and is enabled to produce its special effects are,—either that it gives rise to other bodies by changes in its chemical form, or by acting as an irrespirable gas and causing asphyxia, or by exercising a specific action, just as strychnine does. Dr. Frankland came to the conclusion that nitrous oxide was not decomposed during its sojourn in the body, basing his opinion upon analyses made of the air expired by rabbits when confined in an atmosphere of mixed air and nitrous oxide. In the first stage of asphyxia, that of dyspnoea, there is an increase in the respiratory movements, both inspiratory and expiratory; in the second, predominance of the expiratory efforts, culminating in general convulsions; in the last, exhaustion, with long-drawn inspirations, gradually dying out. The blood-pressure during the first and second stages rapidly rises. Dr. Dudley Buxton has never observed an increase in the expiratory movements when HO_2 has been administered, which are merely increased in number and depth, or expiratory convulsions, notwithstanding the gas has been pushed to its utmost limit, and from a large number of sphygmographic tracings the tension in the arteries has been lower than normal. In experiments upon dogs, Dr. Buxton found that where a trephine hole was made through the skull, during the inhalation of the gas the brain pulsations became more forcible and somewhat hurried; then the brain-substance was seen to swell up, until at last it actually protruded through the aperture; whereas in a similar experiment with the trachea occluded, the brain receded, sinking away from the opening. Other experiments showed that the heart's action was but little interfered with by nitrous oxide, even where the inhalations were pushed until respiration was interrupted. During asphyxia, on the other hand, a rapid and continuous increase in blood-pressure invariably occurred. The dose of nitrous oxide required to produce insensibility varies very considerably in different persons,—a fact which supports the view that nitrous oxide exerts a specific action on the nerve-centres. Dr. Buxton also discusses many other inter-

esting points in the action of the gas, such as the occurrence of hallucinations.—*The Lancet*, April 9, 1887.

THE EFFECTS OF THALLIUM SALTS ON GONOCOCCI, AND ON THEIR EMPLOYMENT IN THE TREATMENT OF GONORRHOEA.

DR. KREIS obtained pure cultures of gonococci by inoculating with gonorrhœa pus a nutritive medium, consisting of agar-agar (Ceylon moss, *Graciellaria* or *Plocaria lichenoides*) and of meat-peptone, and exposing this to a temperature of 36°–38° C. (96.8°–100.2° F.). After a series of carefully and repeatedly controlled experiments, he ascertained that even weak solutions of only one-fourth to one-half per cent. of sulphate of thallium completely destroy the cultures of gonococci. He also tested the effects of the same solutions on divers other kinds of bacteria,—viz., on those in anthrax and glanders, on the staphylococcus aureus, and on urine micrococci, and found that they likewise kill, without exception, all these micro-organisms. PROFESSOR GOLL subsequently practically proved these theoretical conclusions by employing thallium salts with the most satisfactory results in the treatment of gonorrhœa by injections of solutions containing one and one-half per cent. to two per cent. of thallium salts, hereby shortening by fourteen to eighteen days the duration of cure compared with other methods. Referring to these injections, Professor Goll remarks: "For the success of the injections much depends upon the manner in which they are administered. An easily-working syringe with a slightly bulbous point, holding ten cubic centimetres of fluid, ought to be used. Each injection must be double; the first is left to flow off immediately, while the second is retained for a few minutes. It is advisable fully to instruct the patient in this manipulation, the medical attendant making a few injections himself, and having afterwards some made in his presence by the patient. Without these precautions the injections will be but imperfectly made, which is most frequently the case, and explains the many failures of the treatment of gonorrhœa by whatever kind of injection. The well-known complications with irritability of the bladder, cystitis, and especially epididymitis, very rarely occur during a properly carried out treatment with thallium salts, and in the majority of cases not at all. Certain forms of incipient cystitis, pyelitis, and pyelo-nephritis, and similar affections of the urinary organs,

caused by the migration of gonococci into the lymphatic ducts of the mucous and sub-mucous membranes, or by formation of pus and decomposition of the urine, may in many cases, by a combined treatment with thallium preparations, be arrested, or at any rate more rapidly subdued, than by other remedies." Professor Goll further states that he has no experience on the influence of the sulphate of thallium on gonorrhœa in women, which frequently gives rise to very troublesome combinations (see Bumm, *Gonorrhoeische Schleimhaut Erkrankungen beim Weibe*, Gonorrhœic Diseases of the Mucous Membrane in Women, 1885); but he confidently expects favorable results in these cases also. He particularly recommends thallium bougies as very efficacious and easily applied in private practice, especially in the treatment of chronic gonorrhœa. He at present employs for this purpose bougies of butter of cacao with five per cent. of sulphate of thallium. He also tried the tannate of thallium, but entirely discarded it, having found its action, like that of nitrate of silver, too intensely caustic and coagulating. It is of the greatest importance in the treatment of chronic gonorrhœa that the medicament be brought as high up as possible into the urethra, the seat of the disease very frequently being in the posterior portion of the passage. Bougies of butter of cacao are very easily introduced, and it matters little if they break within the urethra, as they may be, without difficulty and perfectly painlessly, pushed upwards to the seat of the disease by means of a common bougie of vulcanite or celluloid. Preparations of thallium will very likely soon be extensively used, and form an important remedy in the treatment of gonorrhœal complaints.—*London Med. Record*, April 15, 1887.

GASTRIC SYPHILIS AND SIMPLE ULCER OF THE STOMACH.

In a paper contributed by A. GALLIARD to the *Arch. Gén. de Méd.* (*London Med. Record*, April 15, 1887) the author discusses the question of syphilitic disease of the stomach, and the influence of syphilis in the pathogeny of ulcer of that organ. The existence of syphilitic affections may be shown by clinical or by anatomical evidence. It has been proved by observation that certain gastric troubles, occurring in the course of secondary or tertiary syphilis, may be successfully treated by mercury and iodide of potassium. M. Galliard, however, does not exaggerate the value

of such facts, since gastric troubles and hæmatemesis are not sufficient to prove a lesion of the stomach itself. Syphilitic disease of the liver, for example, like ordinary cirrhosis, may cause hæmatemesis. The anatomical signs are divided by M. Galliard into disputable and indisputable; the former are gastric catarrh, hypertrophy of the walls of the stomach, and ulceration due to amyloid degeneration. The true syphilitic lesions of tertiary syphilis are gummata, ulcerated or not ulcerated. The author reports two clear cases of gastric syphiloma. Gastric cicatrices found in syphilitic persons may be due to former gummata or to simple ulcers. They are only of moderate value in diagnosis unless gummata be also present, in which case it would be reasonable to consider the scars evidence of bygone specific lesions. When, instead of cicatrices, there are found in syphilitic persons ulcers having the characters of Cruveilhier's ulcer, the question ought to be asked whether the primary erosion was not of a syphilitic nature,—whether, for example, its occurrence was not determined by the gastric catarrh of secondary syphilis or by syphilitic arteritis. It is easy to understand that such an erosion, exposed to the contact of the gastric juice, may be capable of becoming a round, perforating ulcer. It is thus necessary to study with great care, both during the period of ulceration and that of cicatrization, the so-called simple ulcers of the stomach when they are found in syphilitic subjects. In this way the pathogenic influence of syphilis on the stomach, perhaps even the characters of ulcerating syphilides of the stomach, may some day be decided; and when the diagnosis has been made, such affections will be amenable to treatment and capable of cure; but at present the diagnosis is surrounded by difficulties.

Reviews.

A TEXT-BOOK OF PATHOLOGICAL ANATOMY AND PATHOGENESIS. By Ernst Ziegler, Professor of Pathological Anatomy in the University of Tübingen. Translated and Edited for English Students by Donald McAlister, M.A., M.D. Three parts complete in one volume.

William Wood & Co., New York, 1887.

The first part of Professor Ziegler's work on pathological anatomy was given to the English-reading student five years ago, two years later appeared the second part, and, finally, we have the complete work in part

three, issued during the present year. These several parts have now been published in one volume, making a complete text-book, the value of which is not exceeded by any other work in English, notwithstanding the unfavorable method of publication, by which the book as a whole has not received the latest views upon some of the subjects treated in the parts first issued. Having upon the publication of Parts I. and II. noticed their contents, we will now turn to the third part, which includes the pathological anatomy of the urinary organs, the respiratory organs, the central nervous system, and the peripheral nervous system.

The chapters which treat of the pathological lesions of the urinary organs embrace those of the kidneys, bladder, urethra, and supra-renals. A classification of kidney-diseases is made according to the etiology. Thus, 1. Those attributable simply to disturbances of the circulation. 2. Those produced by deposits in the kidney of solid substances, brought to it as such by the blood or precipitated from their solutions. 3. Those degenerations and inflammations due to impurities or disorders of the blood. 4. Those disorders traceable to injurious influences affecting the parenchyma of the kidney through the infundibulum. 5. Those due to tumors or new growths of the kidney. The question as to the nature of uriferous tube-casts is answered by considering them derived from several sources. Hyaline casts or cylinders are said to form in albuminuria as follows: The albumen comes from the glomerule in a soluble form, but within the tubules it may coagulate and give rise to a granular or homogeneous cast; or again, in inflammatory affections of the kidney, the albumen may be derived from the protoplasm of exuded white blood-cells, which is moulded to form casts. Epithelial cells which line the tubules may desquamate and become agglutinated into casts. Granular albuminoid and fatty products of their disintegration give rise to fatty casts. Blood-casts may form in the tubules when hemorrhage has occurred. Waxy casts are believed to be casts which have remained some time in the tubules, becoming more firm and dense. Another source of casts, besides those formed, at least in part, from transuded albumen, is the renal epithelium, which produces a colloid product either in the form of droplets that afterwards unite, or by a transformation of the entire cell when loosened from its place and carried to another part of the tubule.

In the inflammatory affections of the kidney a clinical classification is made of three chief types, viz., acute, chronic, and indurative nephritis. These varieties are again subdivided into other forms; indeed, it seems to us these subdivisions are unnecessarily too many, and occasion confusion in the study of this class of kidney-diseases. A simpler classification is desirable in describing the various pathological conditions of the kidney, which are essentially inflammatory in their nature, since the number of different lesions due to this cause are not essentially a new disease. As regards the attempt, however, to interpret the several forms of nephritis as stages of a single morbid process, we believe with the author that such an explanation cannot be satisfactorily made, and that we are in fact unable in a given advanced renal affection to determine how it began or what stages it passed through.

The section devoted to the respiratory organs includes the pathological lesions of the nasal cavities, larynx, trachea, bronchi, lungs, and also the thyroid and thymus glands.

The answer to the much disputed croup or diphtheria question is as follows: "It will be seen that we make no pathological distinction corresponding to that implied in the clinical terms croup and diphtheria. The specific infective disease diphtheria, when it is accompanied by croupous or superficial diphtheritic inflammation of the larynx or trachea, is the same as the affection clinically described as membranous croup, a term which the pathologist may well dispense with;" or, in other words, the two diseases have the same local pathological lesion.

The chapters on the various affections of the lungs and bronchi are fully abreast of the present period, and the descriptions of the histology of the pathological changes are given in a masterly manner. Four kinds of hæmatogenous infective inflammations are described, and all are considered to probably be due to bacterial infection. "They are true croupous pneumonia, embolic septic (suppurative or gangrenous) pneumonia, embolic tuberculosis, and embolic syphilis." In regard to the significance of Friedländer's pneumonia micrococcus in true croupous pneumonia, Professor Ziegler writes: "The clinical course, the definite duration of the accompanying fever, and the occasional epidemic character of the disease, all point in this direction,"—viz., that croupous pneumonia is the symptom of a specific infective dis-

ease. The definition given of miliary tuberculosis leaves no doubt in the mind of the reader upon which side our author stands in reference to the etiology of this disease. He writes: "Miliary tuberculosis of the lung is set up when tubercle-bacilli enter the circulation in considerable numbers, and lodge in the pulmonary capillaries." At another place he says, "And though our view at present is that the essential and specific irritant in tuberculous phthisis is the tubercle-bacillus, yet it can hardly be gainsaid that in many cases other injurious agencies co-operate with it." The position of the tubercle-bacillus as the etiological factor in tuberculosis is, we believe, to-day an almost universally accepted fact; a few still remain unconvinced, but they are very few, and belong to the class of whom it has been said that there are none so blind as those who will not see.

The chapter upon the structure and functions of the brain and spinal cord is a most valuable one; indeed, we know of no work where so much information may be obtained with so little trouble, and, notwithstanding the obscurity which usually is found in the majority of books when treating of these subjects, Professor Ziegler has succeeded, in so far as our present knowledge has extended, in elucidating very satisfactorily everything bearing upon the anatomy and function of these parts.

Malformations of the brain and spinal cord are briefly, but very interestingly, described, explaining the origin of the various monstrosities, which are, fortunately, but seldom born. Under this chapter are included the different varieties of hydrocephalus and the anatomical conditions upon which they are dependent. In speaking of the significance of the various malformations of the brain, the author states that idiocy is frequently a result; but he further adds, "There is, however, no one variety of malformation which can be assigned as the anatomical basis of idiocy; there is, in other words, no special idiotic brain." This opinion is based upon the circumstance that while extensive alterations from great abnormalities do occasion idiocy, very slight changes may also determine similar symptoms; and, again, grave malformations have existed without giving during life any functional evidence of their presence. It would, therefore, seem that any attempt of neurologists to connect certain forms of idiocy with certain abnormalities is futile. In regard to Benedikt's assertion that in criminals certain peculiarities of the configuration of the cere-

bral surface were constantly met with, in which there was some resemblance to those of the lower animals, our author believes this hypothesis is not tenable, from the fact that anomalies similar to those described by Benedikt occur in persons who have never committed crime. It is also believed that anomalies and malformations of the brain found in insane and epileptic patients are none of them peculiar or pathognomonic of nervous or mental disease, inasmuch as they also are met with in persons whose mental functions are perfectly normal. It is, however, admitted that anomalies of brain-structure are more often seen in persons who exhibit mental defects than in those whose minds are normal.

The question as to the regeneration of nerve-elements of the brain and cord is answered in the negative, at least this is believed to be the case in men, and, therefore, when there occurs a restoration of function, after a destruction of ganglion-cells and nerve-tracts, "it is only by the substitution of equivalent centres and tracts capable of functionally replacing them."

The morbid change present in locomotor ataxia is, according to Professor Ziegler, essentially a degenerative one, and has nothing to do with inflammation. This view is in opposition to that held by most neurologists, who are inclined to consider the lesion a result of the inflammatory process. The etiology of this disease, whether depending upon some congenital or acquired weakness of the centripetal tracts, or upon malnutrition from disturbances of circulation, our author does not decide, since both, he thinks, may apparently be regarded as occasioning the affection. The opinion in reference to the exciting cause of tabes is also undecided, and its real nature thought to be unknown. That syphilis may be an important element in the genesis of the disease is mentioned, but other influences are also thought capable of giving origin to the affection. Having occasion some time since to review the testimony as to the relation between syphilis and locomotor ataxia, we concluded that while it did not supply positive and conclusive evidence of their etiological connection, it certainly led us to believe that there was something more than mere coincidence in the frequency with which the two diseases are associated, and although not quite prepared to accept the positive opinion of those who consider locomotor ataxia, with very few exceptions, due to syphilis, we thought we were justified in concluding that there

must be some not very indefinite etiological connection between these two diseases.

The fatal results of traumatic injuries of the brain are stated to be generally due to the supervention of purulent meningitis and encephalitis, and "it is only when the wound is aseptic or is at once protected from septic infection that we can expect healing without suppuration." The truth of this statement has been most admirably demonstrated during the past year by operative surgery, which has not hesitated to extend itself into the very centre of the brain for the removal of neoplasms, and in some cases without fatal results.

The almost generally accepted view of the location of cerebral tubercles in the adventitia of the arteries, and there forming clusters of cells derived by multiplication from the endothelium of the lymphatics, is believed by Professor Ziegler to be erroneous. The tubercle, according to him, is developed from extravasated leucocytes and proliferous connective-tissue cells; "the adventitia is affected and takes part in the proliferation only in a secondary way, and what has been described as a tubercle due to periarteritis of a pial vessel is, in fact, only a fraction of a tubercle growing near a vessel."

The genesis of gliomata is believed by our author to arise from the neuroglia cells, and a careful examination of specimens of these neoplasms has not convinced him that the view expressed by Klebs, of the active participation of the ganglion-cells in the production of gliomatous growths, is a correct one.

The process by which a divided nerve is regenerated, or the union of a severed nerve, is given as follows: The central end first shows a swelling of some of the axis-cylinders, which is followed by a subdivision of each into from two to five new axis-cylinders; these latter grow in length, and form within the old sheath of Schwann whole bundles of new nerve-fibres. Thus the extremity of the central end of the divided nerve consists at first of new-formed axis-cylinders surrounded by a protoplasmic nucleated sheath, which receives a homogeneous envelope of connective tissue formed from the protoplasmic sheath, between which and the axis-cylinder grows a medullary sheath. This re-formed and growing nerve enters the soft mass of granulations and cicatricial tissue that intervenes between the severed ends. When it reaches the peripheral end, some of whose fibres have meanwhile perished, certain of the

new fibres enter the empty primitive sheaths, but the greater number penetrate the epineurium and perineurium and advance towards the peripheral end organs. It is thus seen that Professor Ziegler adopts the view of the new formation of nerve-fibres from the central end of the old nerve, and that the essential part of the process is the subdivision of the axis-cylinder. He further adds, "The hypothesis that nerve-fibres may grow from granulation-cells or from connective-tissue cells of the perineurium, endoneurium, or epineurium is contrary to all histogenetic analogy." At present the information we possess in regard to this subject is not definite enough to form any positive conclusion, but it would seem that a correct view is possibly to be found in admitting more than one element in the nerve formation, and while we are inclined to regard the axis-cylinder as one, we cannot but believe that the nerve-corpuscles or nuclei on the sides of the sheath of Schwann may also be another element in the regenerative process.

To conclude our notice of Professor Ziegler's and Dr. MacAlister's work,—for to the latter much of the success of the book must be attributed, since his translation could not well be improved, and his additions are such as to give the work an international character, representing the views of both German and English pathologists. We wish to speak of the entire work, and we believe it to be without any exception one of the best treatises for study, for information, and for reference that is at the command of the English-reading profession. The very extensive bibliography which is attached to each article is of itself an invaluable feature of the book; indeed, all the work of the authors is done well. We regret that we cannot say the same of the publisher's work.

In a book treating of pathological histology the illustrations are most important, and should be done in as perfect a manner as possible, since much of the text is a description of the drawings, and much of the student's pathological work is a comparison of his prepared sections of diseased tissues with drawings in works on pathological anatomy. The illustrations in the above volume are bad, indeed, very bad, and no excuse can be made for putting such poor work in the book, since the German and English publications from which they are copied are in every way far superior and suitable to accompany the very able text.

J. H. C. S.

A COMPANION TO THE UNITED STATES PHARMACOPEIA. By Oscar Oldberg, Pharm.D., and Otto A. Wall, M.D., Ph.G. Second Edition.
New York: William Wood & Co., 1887.

As this is the second edition of a well-known book, it does not require at the hands of the THERAPEUTIC GAZETTE any elaborate review, since the well-posted readers of this journal are already familiar with the scope and aims of the book. We are principally interested to know whether this edition has been fully revised, as is claimed on its title-page.

According to the preface, the Companion treats of drugs and medicine used to a considerable extent in the practice of medicine, without reference to their supposed force or want of force. Led by this, we have looked for the articles upon antipyrin and antifebrin,—remedies which are not only used to a considerable extent in current practice but are of very real value, and indeed have taken a first rank among the medical remedies. To our surprise, we have been unable to find either in the body of the work or in the index of it any reference to these remedies. Antipyrin has now been before the profession for four years, and tons of it have probably been administered. *Ex uno omnes discite.*

DRUG ERUPTIONS. By Prince A. Morrow, M.D.
New York: William Wood & Co., 1887.

This book of nearly two hundred pages is a clear, well-written description of the various skin eruptions and inflammations commonly and uncommonly produced by various substances used for medical purposes. It appears to be based not only upon considerable clinical experience, but, what is much more important, a very thorough study of French, English, and German literature. In such a subject the *rara aves* which take their flight before any one man cannot be very numerous, and the study of the records of the world's experience is essential. We note here, as we note almost everywhere, that the world's records mean experience of English-, French-, and German-writing peoples; Spanish and Italian languages seem an insuperable barrier. So far as the Spanish is concerned this is not an important loss, but Italian medicine is rapidly growing in importance.

The value of the present book is especially as a work of reference. Hereafter when some unexpected superficial explosion astonishes the practitioner, he can fly to the present volume with the comforting assurance of relief.

Correspondence.

PARIS.

(From our Special Correspondent.)

The medical and the pharmaceutical professions here are much occupied at present with *hypodermic medication*. As physicians expect great results from the new mode of treating disease, pharmacists are called upon to supply the necessary armaments, and some disinterested persons, as usual, take advantage of the occasion to advertise their products. As regards *quinine*, the question appears to be settled, for the time being at least, in favor of the *hydrochlorate*. At the last meeting of the Paris Society of Pharmacy (April 6) the merits of the rival claimants, the sulphovinate and the lactate, were discussed and summarily disposed of. The *sulphovinate* has the disadvantage of decomposing when kept, and thereby becoming apt to cause abscesses when injected; the *lactate* of being but little soluble when crystallized, so that the solutions have to be made extemporaneously from freshly-precipitated quinine and lactic acid, with some precautions to insure the percentage of active principle. On the contrary, the hydrochlorate is a stable compound, sufficiently soluble, and easily procured from dealers in well-defined crystals, much less liable to adulteration than the ordinary medicinal sulphate. The reason of this comparative purity may be that the sulphate is an old acquaintance of the dealers, in fact, too familiar to them, while the hydrochlorate is a new-comer. But it is unnecessary to borrow trouble; suffice it to say for the present that this salt appears to be the most eligible quinine compound for hypodermic uses, and that it is, in the actual state of science, found in commerce unadulterated with other cinchona alkaloids.

The *petroleum derivatives*, on the other hand, if not active ingredients in the hypodermic medication, still belong to the same system of therapeutics as vehicles for various substances that cannot be conveniently dissolved or suspended in water. But here chaos reigns supreme. Not that formulas and arguments are lacking, for there are floods of them, only practical experience is necessary to establish the value of the products so loudly recommended. Pecuniary interests, it is said, are at stake somewhere. The American and the Russian petroleums are competing for favor; according to some writers the preference should be given to a liquid obtained by exhausting *white vaseline* with ether

at 14° Fahrenheit and distilling off the menstruum. Others appear satisfied with American heavy oils of proper quality, and, again, others condemn American petroleums altogether, and will have none but the Russian or Baku products. It is impossible now to say how far such opinions are justified, but it cannot be denied that some forms of petroleum present great advantages for dissolving or suspending medicines to be administered hypodermically. Before ending the chapter of oily vehicles, however, it is well to say a word of *peanut oil*, which, at least, is subject to no patent right or corporate monopoly. Dr. J. Ley has found this oil equal to the petroleum products in respect to blandness, and superior as a solvent of essential oils, iodoform, and carbolic acid. To purify peanut oil, or to *sterilize* it, as Dr. Ley says, all that is necessary is to bleach it in the sunlight, and to filter it through perfectly neutral bone-black.

The *contamination of water by lead pipes* is one of those topics which always command attention and seem never to receive a satisfactory solution. The reason is that the purity of drinking-water is of too much importance to ever be lost sight of, while the apparently unavoidable use of a poisonous metal for its distribution is a constant source of doubt and suspicion. Not long since a sort of panic occurred in some quarters of Paris because the water department had spoken of incasing with sheet lead the internal conduit of the Arcueil Aqueduct. During the last winter and spring several leaks became apparent in this structure, which, although still new, never was substantial enough. At one time it was even feared the whole thing might fall to pieces, and the remedy proposed by the engineers was to use sheet lead as an inside casing. As the Arcueil Aqueduct supplies one good third of the city, the southern portion, with water from the Vanne River, the purest to be had in Paris, protests many and loud were uttered against the project. The subject has been referred to the *Conseil d'Hygiène*, corresponding to the Board of Health, who will report after due analysis, for it is only a chemical question, since lead conduits may be either dangerous or harmless according to the composition of the water coming into contact with them. Another interesting case was recently related before the Royal Society of Medical and Natural Sciences of Brussels by M. Vande Vyvere, the genial Secretary of the International Pharmaceutical Council, who was so kindly

appreciated by all the pharmacists present at the Brussels International Congress of 1885.

The owner of a house recently went to see him in regard to a lead pipe which had been used only two years for leading water from a well to a pump placed in the dwelling in question. The pipe was all corroded, and the landlord attributing this fact to the bad quality of the metal, wanted to compel the plumber to replace the pipe at his own expense. The plumber vehemently objected,—Brussels and Paris plumbers are not very different from their Philadelphia or New York congeners,—declaring that his lead was of the very best quality, and that the well water was at fault. To prove his side of the case the landlord exhibited a certificate delivered by an analyst who had been called upon a few months before, because the tenants had complained of frequent attacks of colic. The certificate, a model of its kind, is so peculiar that M. Vande Vyvere took a copy of it. It ran as follows: "The water analyzed is clear, limpid, and odorless; it is slightly calcareous; contains no organic matters. This water contains some chlorides."

Notwithstanding so convincing a document, M. Vande Vyvere told the landlord some further investigation was necessary, as the location of the well was not such as to afford a presumption of purity, but just the contrary. Accordingly, the next day, in a visit to the well, a specimen of the water was taken for analysis, and the whole lead pipe removed for examination. The metal was found all indented with small holes, and in some parts the pump-gear so corroded as to resemble a sponge. A whitish coating covered the inside, which, on being removed with a camel's-hair brush, was found to consist of carbonate of lime and carbonate of lead, but chiefly lead.

The analysis of the water was performed on a little more than a gallon of the liquid (four litres). It is unnecessary to relate all the particulars, but the important features are that the water was found to be deficient in dissolved oxygen, contaminated with a considerable proportion of organic matters of animal origin and ammoniacal salts; and what is most singular, with such a quantity of nitrates as to be detected by reagents without previous concentration. On the other hand, lime compounds were in very small proportion, something unusual in Brussels, where hardness is the chief defect of well waters. This hardness, it is true, protects the lead pipes from corrosion, while the presence of nitrates and ammoniacal salts causes the

metal to be rapidly attacked. Hence the well water was at fault, and the colics experienced by the tenants were evidently of saturnine origin. The well was immediately condemned for drinking or cooking purposes. So, for once at least, the plumber was right; but it must be borne in mind this occurred in Brussels.

More or less obscurity has so far surrounded the actual toxic and therapeutical properties of *colchicine*, not to speak of its chemical affinities. A suspected case of poisoning by the alkaloid, which lately occurred in Paris, and in which both chemists and physiologists were obliged to confess their lack of information, has called the attention of scientists to a new and necessary study. Messrs. Mâret and Combemale, among others, having undertaken to supply the deficiency, have published the following results of their experiments. When administered in *toxic* doses to dogs and cats (1) *colchicine* operates as an irritant poison, acting indifferently upon all organs, but still predominantly on the digestive tube and the kidneys; (2) its minimum toxic dose for dogs and cats is smaller when administered hypodermically than by the stomach. In the first case 0.000571 gramme and 0.00125 in the second, to each kilogramme weight of body, are enough to cause death; (3) the hypodermic action is also more speedy than the stomachal; (4) it is eliminated by various excretories, chiefly the kidneys, but the elimination is slow, so that doses otherwise insufficient to cause death, and comparatively small,—0.00016 gramme to the kilogramme of body-weight,—may, when repeated, cause death within five days; (5) *colchicine* occasions congestions of the articular extremities and bony medulla.

The foregoing experiments were performed upon five dogs and two cats. To investigate the *therapeutic* effects of *colchicine*, eight men, two of them arthritic, three dogs, and one cat were experimented with. The following are the conclusions of the writers: When administered in therapeutic doses (1) *colchicine* acts, according to the dose, either as a diuretic or as a purgative, and does so owing to a congesting and irritant action upon the kidneys and the digestive tube; (2) the effects are the same whether the substance is ingested hypodermically or by the stomach, but they are more speedy and require smaller doses in the first instance than in the second. Man is three times more sensible to the effects of *colchicine* than dogs and cats are, as the

total diuretic dose for him may be fixed at 2 or 3 milligrammes, and the cathartic at 5 milligrammes; (3) colchicine increases the excretion of uric acid, and produces, on articular surfaces and bone medulla, congestions giving rise to two sorts of effects that it is of some interest to compare with the purgative effects to account for the mechanism of the alkaloid's action in certain diseases, gout especially. Colchicine decreases the quantity of the uric acid contained in the blood, and produces a substituted irritation on a level with the articular surfaces. But its tendency to accumulate in the economy, and its great toxic power, render great caution in its employment necessary.

On the other hand, chemists have so far supplied no characteristic test for identifying colchicine.

In no way, perhaps, do medical ethics and jurisprudence differ so much in different countries as in regard to *professional secrets*. To speak only of the United States, in some parts the medical secret is scarcely recognized by law, while it is nowhere enforced. In France a very different jurisprudence prevails, for the law edicts a penalty of from one to six months' imprisonment, with a fine not exceeding five hundred francs (one hundred dollars) against all physicians, surgeons, pharmacists, and midwives guilty of divulging the secrets that have come to their knowledge in their professional capacity. And the law is not a dead letter, for it never was applied more strictly than it has been recently. Less than two years ago, Dr. Watelet, after the death of M. Bastien Lepage, the celebrated artist, whom he had attended, felt offended at a criticism published in a Paris paper. To vindicate himself he wrote a letter to the *Matin* newspaper, detailing at some length the disease, treatment, and cause of death. But for so doing he was, without any intervention of the Lepage family, prosecuted by the district attorney (*Procureur de la République*) and summoned before the Correctional Tribunal, together with the publisher of the *Matin*. The court would not admit good faith or the lack of evil intent as sufficient excuse, but only as a mitigation of the offence, and sentenced the doctor to one hundred and the publisher to sixteen francs' fine. Both appealed, and a few months later the sentence was confirmed by the Court of Appeals. Of course, in all such cases the fine itself is of slight consequence, but the costs are considerable. Another case, which occurred in February last, is no less interesting because it shows the rule works both ways. It was as fol-

lows: D., a resident of Besançon, had insured his life for five thousand francs (one thousand dollars). After his death the heirs applied to Dr. X., the deceased's physician, for the requisite certificate enabling them to collect the insurance money. Said certificate, according to a clause of the policy, is to indicate the nature and duration of the disease which caused the death. X. refused to do anything of the sort. Perhaps he had in mind the fate of his Paris professional brother, perhaps he had some other reason. By the way, it may be remarked that French physicians are not quite agreed as to their duties in respect to the death certificates of persons insured by companies. Some doctors think they may divulge the nature of the disease when it is not of a hereditary or disgraceful character. Others, and with them Dr. Brouardel, are of opinion that the family physician must in all cases remain silent. For if in some cases he should consent to give certificates, and refuse in others, his refusal would become equivalent to the very worst certificate. By such a course he might expose the memory of his patient and the soundness of his offspring to most injurious suspicion.

However it may be, our Besançon physician stoutly refused to give the certificate as requested. Thereupon the heirs began a civil action against him and the insurance company, including both as co-defendants, so as to obtain the money either with or without the certificate. Before the court the doctor's plea was the penal statute enjoining professional secrecy; that of the company, the policy clause providing for the production of a death certificate. The court accepted the doctor's defence, exonerating him, free of all costs, and ordered the company to pay the full amount demanded, together with all the expenses and costs of the lawsuit.

BERLIN.

(From our Special Correspondent.)

Although during the last few weeks the whole population of Germany was interested in the preparation for and the celebration of the emperor's ninetieth birthday, yet a few scientific men were interested in a subject quite different. The "art of starvation" was practised by a Norwegian named Cetti, who finished a fast of eleven days on the 22d of March. It may be an occasion for astonishment that such a fast is considered worthy of notice. America possesses a Dr. Tanner who

fasted for a much longer period, and many others, equally foolish, have followed his example. This Cetti, however, fasted for the cause of science, and no less a person than Virchow tendered him his thanks in the name of science before the whole medical association of Berlin when he read the notes which he had taken of the case, and stated the benefits which he believed might follow such a course of prolonged abstinence. It happened as follows: Cetti had intended to give an exhibition to demonstrate his "hunger-cure." He probably considered it expedient to solicit the notice of well-known men in order to give his experiment more of a show of being a scientific investigation. In a most remarkable degree he was enabled not only to attract the notice of able men, but they watched over and controlled his "hunger-cure."

If it had been possible to conduct the investigation in a physiological laboratory perhaps no objection would have been made, but as the whole machinery of the affair was to be made public, the police forbade the exhibition. Cetti starved, nevertheless, but entirely for the benefit of science, and not less than five learned men and a staff of fifty young physicians watched him, day and night, took the weight of his body, measured the sensible and insensible loss, controlled the loss of volume, examined his blood, used the dynamometer in examination of his strength, and examined his urine. The man was exhibited by Professor Senator, who was at the head of the committee of observation, on the 23d of March before the Medical Society: there was, naturally enough, very little that was noticeable about him. The results of the observations will not be made public for some weeks. The full importance for clinical purposes of these observations will be noticed later when we have full particulars.

The therapeutic field of German medicine has been greatly stirred of late, and as the agitation has undoubtedly excited interest in America, the writer will give it extended notice in the present letter. The question of the hour is the treatment of fevers, chief among which is abdominal typhus.

In the last few years we have had a high tide and flood of antipyretic remedies, each of which has brought its own recommendations, and there have been many authors who have thrown down the gauntlet in favor of the use of one or the other of the so-called antipyretics in diseases caused by infection. But after careful examination not one of these remedies, in a strict sense of the word, has

been able to cope with typhoid fever, at least in the sense in which quinine controls malarial fever, supposing malarial fever to be controlled when its principal symptoms are suppressed. In the last few weeks the question has been much discussed whether the cure for fever lies in the antipyretics now used in medicine.

Brand, the first of his time who practised the cold-water treatment of typhoid fever, in an extended article, which is being published in the *Deutsche Medicinische Wochenschrift*, raises his voice in favor of the method inaugurated by him and against antipyretics. Other authors, among whom we will mention only Ebstein, Senator, Gläser, have given testimony in favor of the "expectant methods," and Leyden, Fraentzel, and others favor their view. The matter will be critically studied, and doubtless such investigation will lead to the abandonment of many of the antipyretic methods now in vogue.

With the progress of study in bacteriology has arisen the question, which has received much attention during the last few years, as to whether an abortive treatment, in diseases caused by infection, is possible; and in this connection Schörlein, and later Liebermeister and others, have recommended naphthalin, as well as calomel, for their disinfecting properties when introduced into the large intestine, in the abortive treatment of infection. The thorough study of these drugs and their action cannot fail to be a progressive step, even if it should lead to their abandonment. In this connection we quote from the results given by Professor Fürbringer, of the department of internal medicine at the hospital called the "Friedrichshain," on March 7. He compared twenty-five cases of typhoid fever treated with naphthalin to a like number treated expectantly, in regard to the duration of the disease, the mortality, and complications; the results were unfavorable to the use of naphthalin. An entirely new method of examination was followed, which consisted chiefly in the investigation of the dejecta for bacteria.

Fürbringer examined the stools of those patients treated with naphthalin as well as the stools of patients treated by the expectant method. The results when calculated showed in round numbers per average, in a milligramme of feces from a patient suffering from typhoid fever who was not treated by naphthalin, one hundred and twelve thousand bacteria; in the stools of a patient who was given naphthalin, ninety thousand bac-

teria; in both instances the schistomycetes, bacteria capable of abundant increase, were present. In this result there is, it is true, a slight advantage in favor of naphthalin, but there was not a trace of disinfectant effect produced upon the stools of a typhus patient when colonies of typhoid bacilli have been found in cultures made from stools of those who took naphthalin, and when in addition even a multiplication of micro-organisms greater than that in typhus abdominalis was observed in naphthalin stools. An analogous investigation on the use of calomel produced quite the same results. If, however, as is claimed, calomel has an incontestable effect upon certain cases of typhoid fever, we may expect some results upon the typhoid bacilli from its use. For a detailed discussion upon this subject we must refer the reader to the original lecture in the *Deutsche Medizinische Wochenschrift*.

Under the direction of Professor Fürbringer the diuretic effect of calomel in diseases of the heart, which has been so highly extolled by Jendrassik, has been investigated at the Friedrichshain hospital. The results corroborated the assertions of Jendrassik in the cases which were so treated. Leyden has also made a study of the diuretic effects of calomel. In those cases of hepatic cirrhosis with ascites he obtained no result in one; in a second some relief followed its use; in the third a distinct and lasting result was obtained. In diseases of the heart, with diminished diuresis and dropsy, Leyden considers calomel to be a decidedly valuable remedy, which, although not invariably certain, in many cases has a decided diuretic effect.

The writer closes the present letter with a reference to the widespread interest now existing in Berlin over the study of myxœdema. A few weeks ago, on his return from a journey to England, Virchow gave the Medical Society of Berlin a minute account of the recent investigation, especially Horsley's, of this disease, which, until now, has been comparatively unknown. Cases of myxœdema have been recently reported from all quarters of Germany, which had been previously overlooked from ignorance of its symptoms.

The general inquiry and interest awakened in England regarding this disease cannot be disregarded from the stand-point of German medicine.

BERLIN, March 24, 1887.

ANTIPYRIN AS AN ANTIPYRETIC.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—I have read from time to time different experimenters' researches in regard to the new remedy antipyrin, and have been pleased and benefited as well. I think the drug is destined to fill an all-important place in the physician's armamentarium. Even with the little experience I have had with the drug I would not do without it. Of its antipyretic action there can be no doubt, and in any case of a sthenic nature its action is excellent.

On December 13, 1886, I delivered a woman of a large male child. The woman was a primipara and 27 years old. On the third day after delivery had a temperature of 102° F., and, notwithstanding I used the usual treatment indicated under such circumstances, the temperature on the sixth day after the birth of the child was 106° F. There was pelvic and diffused peritonitis. I became fearful for the safety of my patient, and resolved to try antipyrin, which I prescribed in 15-grain doses, dissolved in cinnamon-water q.s., every four hours. After the third dose the temperature was down to normal, and no bad after-effects, such as chilliness and nausea, were observed. The intermission lasted twelve hours. In the intermission I gave quinine and salicylic acid. The following day the temperature came up again to 103° F. I again used the antipyrin in 8-grain doses every three hours. After the third dose the patient was sweating profusely, and the temperature receded to half a degree below normal; gave stimulants and other necessary treatment; put woman on proper management, and she got well promptly.

I treated another case in January of the same kind with the same results.

I have used antipyrin in four cases of malarial fever where I thought it indicated, and with the happiest results. It is good in high temperature of the exanthemata, especially where in measles you have an alarming temperature. You can soon reduce it with safety by the use of this drug. A convenient formula for these cases in children is—

R Antipyrin, ℥ii¼;
Aq. cinnamon., ℥ii. M.

Sig.—One teaspoonful every two hours as needed to control fevers.

There is no doubt of the utility of antipyrin in many cases of hemicrania. Usually one dose of from 10 to 15 grains will suffice to relieve an attack. I have had excellent

success in treating headaches of the ordinary types by prescribing caffeine citrate in 1- to 2-grain doses, and if three or four doses of that do not relieve, then resort to the antipyrin.

My experience with the drug, though quite limited, has been very flattering as to the utility of what promises to be one of the great therapeutic discoveries of this age.

Yours,

J. Z. SCOTT, M.D.

SCANDIA, KANSAS, April 12, 1887.

ABORTION FOLLOWING THE USE OF POTASSIUM PERMANGANATE.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—I saw in your last issue of the THERAPEUTIC GAZETTE an article entitled "Abortion following the Use of Permanganate of Potassium." I have a similar case I wish you would publish in the next issue. Last July a colored woman applied to me for treatment, and stated that her menstrual periods had never been regular before marriage, and during the three years she had been married she had gone three months at a time without menstruating. At the time she applied to me it had been one year since she menstruated the last time, but during that time her general health had been very much depreciated. I at first gave her tonics, thinking, perhaps, by building up her general health it would set things aright. After keeping her on the tonics for some time, I found she derived no benefit from the treatment as regards the menstrual periods, although her general health was greatly improved. I then put her on permanganate of potassium, 2 grains three times a day (having no idea that she was pregnant). After she had been taking it a few days I was summoned to see her, and upon my arrival I found that she had aborted, and the foetus looked to be about two months old.

Notwithstanding some good authorities say that the permanganate does not have any influence upon the gravid uterus, yet I believe it caused abortion in this case.

Very respectfully,

J. J. MANN, M.D.

NASHVILLE, N. C.

Notes and Queries.

NETTLE JUICE.

Les Nouveaux Remèdes states that the best remedy for hemorrhages of all kinds is nettle

juice. It is better than tannin, chloride of iron, sulphuric acid, hydrochloric acid, or ergot. The illustrious Chomel said, "This remedy is the most certain to stop hæmoptysis and all hemorrhages."

The difficulty heretofore has been that the remedy was not available, because it will not keep. However, a pharmacist, M. Peneau, has conceived the happy idea of preparing a syrup from the juice. This is done at a time when the plant is in full vigor. In this form the medicine does not alter, and keeps indefinitely.—*National Druggist*, April 22, 1887.

FORMULÆ FOR LANOLIN OINTMENTS.

WULFSBERG, of Christiania, gives the following formulæ in the *Therapeutische Monatshefte* for March, 1887:

R Lanolini, $\text{ʒiij}\frac{3}{4}$;
Cetacei,
Olei amygdalarum, aa ʒiv ;
Olei bergamot., gtt. v;
Olei lavand., gtt. xv. M.
F. unguentum.

This may be used as a pomade.

R Ung. picis liquid., ʒiv ;
Lanolini, $\text{ʒxi}\frac{1}{4}$. M.
F. unguentum.

This was used with good results in a case of chronic eczema, which was caused by exposure in the tropics and had resisted other remedies.

A ten per cent. ergotin and lanolin ointment was found excellent in the treatment of hemorrhoids.

A ten per cent. mixture of ung. cinereum and lanolin, again mixed with lanolin as a diluent in the proportion of one in twenty, was very successfully used in cases of pediculi pubis, and also to promote the absorption of infiltration, as in the case of scars and infiltrates occurring in the course of the healing of wounds.

RELATIONSHIP BETWEEN HYDRASTINE AND NARCOTINE.

M. FREUND and W. WILL have obtained very interesting and important results during a study of the chemical nature of hydrastine from *Hydrastis canadensis*.

Perrins discovered hydrastine (which occurs alongside of berberine) in the mother-liquid left after the separation of berberine by means of dilute acids. The mother-liquid

is cautiously neutralized with ammonia until a permanent precipitate of a dark-colored resin forms, which does not redissolve on stirring. The liquid is then filtered, and ammonia added to the filtrate, when a yellowish-brown precipitate separates, which is several times recrystallized from alcohol, and then constitutes hydrastine, forming colorless, shining prisms.

Shortly afterwards the base was examined by Mahla, who assigned to it the formula $C_{22}H_{23}NO_6$.

Freund and Will have met with difficulties in the preparation of hydrastine. The above-mentioned yellowish-brown precipitate is produced in copious quantity, but it is difficult to recrystallize; nor could the authors obtain a yield of one and a half per cent. from the root, as stated by Perrins. For this reason they preferred to extract the finely-powdered root with ether. The residue left on evaporation of the latter is dissolved in hot alcohol, and the filtrate allowed to cool, when crystals of nearly pure hydrastine separate. The base is remarkable on account of the ease with which it crystallizes. It forms crystals belonging to the rhombic system, melts near 132° C. (269.6° F.), and is lævogyre in chloroformic solution, but dextrogyre in aqueous solution made with the aid of hydrochloric acid.

When hydrastine is oxidized either with permanganate of potassium or with nitric acid it is partly converted into *opianic acid*, identified by ultimate composition, melting-point, and all other properties. The oxidation by permanganate is made as follows:

Five grammes of hydrastine are dissolved in an excess of hydrochloric acid, the solution diluted to about two litres, and gradually mixed with a cold solution of ten grammes of permanganate of potassium in two litres of water. The mixture is then rendered faintly alkaline with sodium carbonate, filtered, and strongly concentrated. On supersaturating with diluted sulphuric acid a substance is deposited which is removed by filtration. The filtrate is diluted with ether, and the residue of the ethereal solution, together with the substance remaining on the filter, recrystallized from boiling water, being at the same time treated with animal charcoal. The colorless needles thus obtained correspond to the composition $C_{16}H_{11}O_6$, and are *opianic acid*.

With nitric acid the following process was adopted by the authors, as they wished to ascertain what nitrogenized by-products were formed during the reaction.

Ten grammes of hydrastine were cautiously

warmed with fifty cubic centimetres of nitric acid (spec. grav. 1.300) and twenty-five cubic centimetres of water to 50° to 60° C.—(122 – 140° F.), and kept at this temperature until a small portion tested with ammonia ceased to produce a precipitate. Care must be taken to avoid any considerable evolution of carbonic acid. After standing some time, the cold solution deposits a large amount of colorless crystals, which are *opianic acid*. On supersaturating the filtrate with very concentrated potassa solution, a white, voluminous precipitate is produced, which soon becomes crystalline. After being dried and recrystallized from benzol or acetic ether, crystals of a new base are obtained, which has been analyzed, but needs further study.

Since *opianic acid* is thus one of the decomposition products of *hydrastine*, and the same is obtained from *narcotine*, a very close relationship of these two alkaloids, one from *hydrastis*, the other from *opium*, must be suspected. It is true that the basic portion of the decomposition of *narcotine*, viz., *cotarnine*, is not identical with the base above described, yet it is so very similar that (as the authors say) it would be taken for *cotarnine* were it not for the analytical results.

The relationship of hydrastine to *narcotine* is, however, further demonstrated by their behavior towards potassa. If powdered hydrastine is introduced into a concentrated watery solution of potassa, and heat is cautiously applied, after the water has evaporated the hydrastine melts to a viscid mass. On removing the latter mechanically it becomes hard on cooling, and is then easily soluble in water. When the aqueous solution is neutralized by a diluted acid, unaltered hydrastine separates again. The same has been observed by Wöhler to occur in the case of *narcotine*. Another remarkable coincidence is that both alkaloids deviate the ray of polarized light to the left in chloroformic solution, but to the right in an acid aqueous solution.

If the residues left after the separation of berberine and hydrastine are strongly concentrated, acidulated with sulphuric acid, and the filtrate shaken with ether, large crystals of a faint yellow color will be obtained on evaporation. This substance may be obtained more easily by shaking the liquid extract of the root with ether before the removal of the berberine and hydrastine. On analysis this substance proved to be free from nitrogen and neutral, and therefore not identical with the other alkaloids supposed to exist in *hydrastis*. So far it appears to be a substance

partaking of the properties of lactones.—*American Druggist*, March, 1887.

A HEROIC METHOD OF PRODUCING EMESIS.

We have received from a Boston correspondent a letter from which the following extract is taken :

"I have never yet seen in any work on materia medica, therapeutics, or toxicology the following method of emptying the stomach in cases of opium-poisoning. I have found it rapid and effective in two cases. It is entirely mechanical, but acts in a very short time. Four to six ounces of sodii bicarb. stirred well into a goblet of water and swallowed. In a few moments follow it by a goblet of good vinegar. The result is that a perfect fountain of the mixture, with the contents of the stomach also, flies out of the mouth into the basin. I first heard of it from Dr. Henry G. Clark, of this city."

[We think that this method of causing emesis has not been widely practised in the profession. It is certainly very heroic, and to one who has never seen the play of this human geyser somewhat appalling. Probably in a strong, vigorous patient the plan would not be able either to produce fatal strangulation or rupture of the stomach.—EDS.]

PHYSICAL AND CHEMICAL PROPERTIES OF ANTIPYRIN.

PROFESSOR V. A. TIKHOMIROFF, of Moscow, says (*Proceedings of the Moscow Physico-Medical Society*, Nos. 5 and 6, 1886) that a pure preparation of antipyrin is rapidly and completely dissolved in water, the solution having a neutral reaction. The most characteristic reaction of the drug is that a very weak, slightly yellowish solution of perchloride of iron becomes dark reddish brown in color when a small quantity of antipyrin is added to it. On the subsequent addition of a drop of sulphuric acid the mixture becomes completely discolored. Another characteristic property of the drug is that on mixing a watery solution of it with an excess of nitrous acid (or rather with a mixture of KNO₃ and HCl), a green precipitate, bearing the name of "iso-nitroso-antipyrin," appears, and forms spherical masses, which, as seen under the microscope, closely resemble colonies of yeast-fungi (*saccharo-mycetes cerevisiæ*). This appearance is produced by the aggregation of

extremely minute crystals having a double refraction. The precipitate is soluble in caustic alkalies and ammonia, the solution being of a greenish-yellow color.—*Brit. Med. Journ.*, February 26, 1887.

REACTIONS FOR DUBOISINE, HYOSCYAMINE, AND ATROPINE.

We take the following from *Rundschau* (Prag): The reagent employed is a five per cent. solution of corrosive sublimate, using fifty per cent. alcohol as solvent. Two cubic centimetres of this solution, with one milligramme atropine dissolved in one to two drops of water, by immersion in a hot water-bath, give a reddish-blue precipitate.

With pure crystallized *hyoscyamine* treated in the same manner a clear solution results, which becomes slightly opalescent upon heating for a time in a water-bath.

With pure crystallized *duboisine* under same conditions a white cloudiness and white precipitate occurs when heated.

With amorphous (syrupy) *duboisine* a dense white cloudiness is produced, turning canary-yellow when heated.

With *hyoscine*, isomeric base with *hyoscyamine* and *atropine*, the solution remains clear like water, and does not change when immersed in a water-bath for a considerable time.—*National Druggist*, March 4, 1887.

FATAL RESULT OF INTRA-UTERINE MEDICATION.

DR. OTTO ENGSTRÖM, of Helsingfors, relates the following case in a Swedish medical journal. A woman, aged 37, had suffered from persistent metrorrhagia. The uterus was retroflexed, but no signs of past or present inflammation could be discovered. It was replaced and scraped out with a Simon's sharp spoon, two small spoonfuls of hyperplastic tissue being removed. A solution of iodine in iodide of potassium at 45° C. was then injected, the relative proportions of iodine, iodide of potassium, and water being 1, 2, 30. No fever and scarcely any pain followed. In five days' time a second injection was used, the temperature being 40° C., and the relative proportions of iodine, iodide of potassium, and water 1, 2, 10. No pain was experienced, and the patient walked up- and down-stairs. On the evening of the second day, however, a rigor came on, followed by pyrexia, abdominal tenderness, diarrhoea, and

convulsions, death occurring two days later. At the necropsy there were found bronchopneumonia, chronic œdema of the lungs, endocarditis, and purulent peritonitis. The substance of the uterus was soft, friable, and gray-colored, containing specks of blood and lymph. The peritoneum over the uterus was of a yellowish-red color and covered with puriform matter. The Fallopian tubes and their fimbriated extremities were not dilated or particularly reddened, and the mucous membrane presented no abnormality. The os uteri was too small to admit a fine probe. A large quantity of pus occupied the peritoneal cavity. Dr. Engström does not think any of the injection can have passed into the tubes, still less into the peritoneal cavity, and believes that the fatal peritonitis was due to an extension of the inflammation directly from the uterine wall to the peritoneum.—*Lancet*, April 16, 1887.

MELON-ROOT AS A SUBSTITUTE FOR IPECAC.

The *Journal de Pharmacie* says that Torosicvitz obtained the emetic principle of melon-root by treating the aqueous extract with alcohol. He calls it melon emetine.

Properties: Brownish hard mass with shining fracture, very deliquescent; its aqueous solution has a slightly sharp, bitter taste; it is indifferent to acids and alkalies; it colors ether. Alcohol dissolves it instantly, and it is precipitated by acetate of lead and by infusion of nut-gall. Solution of ammonia or potassium dissolves it readily.

Maximum dose of melon-root powder, 25 grammes. Dose of melon emetine, 9 centigrammes. This produces vomiting.

The cultivated plants were used for these experiments. The wild plants are much more active.—*National Druggist*, April 27, 1887.

USE OF SOME NEW REMEDIES.

Osmic acid—best administered in pill form (made up with Armenian bole). The dose is $\frac{1}{80}$ grain, which may be repeated several times a day. Used in epilepsy and sciatica. Agaricine—best administered in combination with Dover's powder. Dose $\frac{1}{2}$ to $\frac{1}{4}$ grain. Used for night-sweats. Aloin—from $\frac{1}{4}$ of a grain to $3\frac{1}{2}$ grains in pill form. Antipyrin—dose from 75 to 90 grains, divided into three portions, one of which is to be taken every hour. Bismuth salicylate—dose 5 to 7 grains, in pill

form. In typhoid this dose may be doubled and repeated every hour up to ten or twelve times. Cannabinon—from $\frac{2}{3}$ to $1\frac{1}{2}$ grains. Best administered mixed with finely-ground coffee. Sedative and hypnotic. Colocynthin—used subcutaneously. The dose is from $\frac{1}{4}$ to $\frac{1}{2}$ grain. It may also be administered in pill form by the mouth, the requisite dose being from $\frac{1}{4}$ to 1 grain. Convallaramine—internally, in pill form. The dose is from $\frac{1}{4}$ to $1\frac{1}{2}$ grains. Euonymin—best given in pill form, combined with extract of belladonna or hyoscyamus. The dose is from 3 to 10 grains. Nitro-glycerin is best given in alcoholic solution. The dose is from $\frac{1}{100}$ to $\frac{1}{80}$ grain, repeated several times a day. Rosbach prefers ether as a solvent. His formula for its use is as follows: Dissolve $1\frac{1}{2}$ grains of nitro-glycerin in sufficient ether, and add the solution to a mixture consisting of 2 ounces of powdered chocolate and 1 ounce of powdered gum arabic. Mix very thoroughly and divide into 200 pastilles. Each pastille will thus contain $\frac{1}{80}$ grain of nitro-glycerin. Used in angina pectoris, and as a diuretic. Picrotoxin—in aqueous solution. Dose from $\frac{1}{4}$ to $\frac{1}{2}$ grain. Used in epilepsy. Sulphate of thallin may be given dissolved in wine or water (with some corrigent). The dose is from 4 to 8 grains, or 1 grain every hour.—*London Med. Record*, April 15, 1887.

MYRTOL.

Myrtol is obtained from the distillation of the leaves of the myrtle; it is a liquid possessing the characteristic perfume of the plant. It is of less density than water, evaporates at the ordinary temperature, stains paper, but the stains disappear entirely. It has a warm, slightly acrid taste, soon followed by a sensation of freshness. It is said to be an excellent disinfectant and an energetic antiseptic, to stimulate the digestive functions, and to increase the appetite. In moderate doses myrtol acts as a sedative to the nervous system. It is eliminated by the respiratory and urinary passages. Myrtol appears to have the advantage over the balsams of not upsetting the stomach, thereby enabling it to be employed for a long time without leading to objectionable effects,—e.g., dyspepsia. M. LINARIS has had globules of myrtol prepared, each containing fifteen centigrammes of the pure liquid. The remedy does not appear to cause the same effects at all periods of diseases of the respiratory passages. In order to obtain

the best results it should be employed with a view to combating subacute or chronic catarrhal affections, or it may be given at the termination of an acute attack of bronchitis when the fever has subsided. Another indication for its employment is an abundant opaque muco-purulent secretion. In these cases the secretion is diminished and rendered less purulent. M. Linaris has employed myrtol in chronic fetid bronchitis, catarrhal bronchitis, catarrhal asthma with paroxysmal attacks and palpitations, capillary bronchitis, and dilated bronchi. The average daily dose was six of the globules; they should be taken after meals,—two in the morning, two in the daytime, and two at eventide.—*Lancet*, March 26, 1887.

PHENOL-MERCURY.

A new mercurial preparation has been lately introduced which bears the name of phenol-mercury. It is given in pills containing 0.02 gramme, of which the dose is at first two, increased to six daily. Stomatitis is said to be only rarely produced by its administration. Phenol-mercury is prepared by mixing an aqueous solution of one hundred and thirty-two parts of phenol-potassium with one of two hundred and seventy-one parts of mercuric chloride, when a reddish-orange precipitate is thrown down. This is washed on a filter until the filtrate no longer gives a reddish color on the addition of potassium iodide. In drying the color becomes lighter, and the powder retains only a faint odor of phenol. The phenol-potassium mentioned above is made by mixing alcoholic solutions of ninety-four parts of crystalline carbolic acid and fifty-six parts of caustic potash, and evaporating to dryness. It is a hygroscopic compound and difficult to keep, and should therefore be freshly prepared when required.—*Provincial Medical Journal*, April 1, 1887.

SWEET SUMACH.

The fluid extract of the root-bark of the sweet sumach, *Rhus aromatica*, an Anacardiacea indigenous to the United States of North America, has lately been successfully employed in nocturnal enuresis of children. It acts as an excitant on the non-striped muscles of the bladder, the uterus, and of the inferior portion of the digestive canal, and beneficial effects have likewise been obtained from it in hemorrhage of the bladder, the uterus, and the rectum, as well as in atonic diarrhoea.

Dr. Unna recommends, from three years' experience, this extract in enuresis of children, for which it acts as a specific. He prescribes to infants and children, up to two years of age, 5-minim doses in the morning and at bedtime; to children from two to six years of age, 10 minims twice daily; and to older children 15 minims twice daily. He never observed any injurious concomitant effects, even after its uninterrupted use during several months. Its tonic effects, however, are not permanent, the paresis of the sphincter muscles of the bladder returning soon after discontinuing the remedy. It ought, therefore, to be given daily as a rapidly-acting palliative until the weakness has been gradually overcome by other adequate measures (training to the habit of regularly emptying the bladder, cold baths, douches, cool beddings, etc.), and only then to be gradually withdrawn.—*London Med. Record*, August 15, 1887.

TREATMENT OF CATARRHAL JAUNDICE.

DR. GLUZINSKI, writing in a Polish journal, states that in cases of catarrhal jaundice he has found excellent results follow the treatment recommended by Krull,—viz., the repeated injection into the bowel of large quantities of cold water. This increases the peristaltic action of the intestines, and removes any mechanical obstacle to the flow of bile. Again, as has been shown by Röhrig and Mosler, who injected large quantities of cold water into dogs, the bile is thus rendered both more liquid and more abundant, so that it more easily overcomes any obstruction. At first water at 59° F. is injected into the bowel until the patient complains of a feeling of distention in the abdomen. He is then made to retain it as long as possible. Most patients manage to retain two litres for from a quarter to half an hour. The next day the enema is repeated, but with water about 4° higher. The temperature is again raised on each succeeding day, but when 72° have been reached no further increase is made. The reason of the increase is that the repeated introduction of cold water is apt to irritate the mucous membrane of the bowel. Altogether four or five enemata are sufficient to produce the desired effect. The increase of the biliary secretion may be judged of by the color of the fæces. Of course, the diet is attended to in order to prevent a recurrence of the affection.—*Lancet*, April 23, 1887.

HYGIENIC THERAPEUTICS—A LECTURE ON KINESITHERAPY.

BY PROFESSOR DUJARDIN-BEAUMETZ, Paris, France.*

GENTLEMEN:—Last year, in a series of lectures, I undertook the study of alimentary hygiene; this season I intend to complete the subject of hygienic therapeutics by considering the benefits derivable from movements and exercise, air, water, and climate in the treatment of diseases. In the present series, then, I shall successively treat of kinesi-

therapy, massage, hydrotherapy, aerotherapy, and climatotherapy. I hope to show you that these hygienic agents, as well as alimentation, have an important and often preponderant rôle in the treatment of a great number of affections; I hope also that you will receive with the same interest and the same indulgence this second part of my course on hygienic therapeutics.

I shall begin by the study of exercise and of movement as applied to the treatment of diseases. To the sum of these curative means has been given the name of *kinesitherapy* (from *κίνησις*, movement, and *θεραπεία*, treatment). I shall devote this first lecture to the history of gymnastic therapeutics, and the physiological phenomena developed by movement; then, in

* Delivered in Cochin Hospital, and printed from advance sheets.

the next lecture, we shall complete the subject by the examination of the methods and modes of application of kinesitherapy.

I do not intend to go over the entire history of gymnastics; you will find in the Report of Hillairet, in Collineau's "Gymnastics," and in the treatise of Dr. Chancercel on "Medical Gymnastics," published in 1864, all the more important data connected with kinesitherapy.* But it is especially in that remarkable work of Dally, Sr., entitled "Cinésiologie," from which all subsequent writers in this department of therapeutics have drawn so largely, that you will see an exhaustive handling of this whole subject. Finally, in the article of Dally, Jr., in the "Dictionnaire Encyclopédique," you will find much valuable information on this matter, and this especially from a physiological point of view. I shall, then, content myself with giving you a brief summary of the leading facts in the history of medical gymnastics, being persuaded that such an abridged statement will not be devoid of interest and profit.

Prehistoric man, as I told you in my last year's course, can hardly be said to have employed, in the treatment of diseases, any agents except such as are derived from hygiene, and among these must be included movement and exercise. Obligated to contend against the inclemency of the seasons, and against animals physically better endowed than himself in the struggle for existence, primitive man was obliged for his own support and defence to devote himself to a kind of natural gymnastics, which gave him extraordinary strength and agility. There is evidence, also, that he was fond of those dances which are now so common among all savage tribes, as the Australian, the Neo-Caledonian, the Tasmanian; dances inspired, according to Letourneau, by the chase or war. In their hunting dances, these primitive men imitate the actions of the animal which they are wont to pursue, and all the exciting details of the chase; it is a dance of joy and hilarity. As for the war-dance, all savage tribes are wont to prepare themselves for the battle by a pantomimic rehearsal of the fight, and there are innumerable forms of the martial dance, from the cannibal war-

dance of the Neo-Caledonian to the Pyrrhic of the Greeks.

These war-dances are interspersed with chants, and one of the most curious is that which De Rochas has put in the mouth of the Neo-Caledonians: "Shall we fight the enemy? Yes. Are they strong? No. Are they valiant? No. Shall we eat them? Yes."

But at the very dawn of human history, it is among the inhabitants of China and the Indias that we find the first indications of the co-ordination of elements derived from exercise and movement for a determined hygienic purpose. Nearly three thousand years before the Christian era, under the reign of the Emperor Hoang-Ti, appeared a treatise entitled "Cong-fou, or the Art of Man," where were set forth at length all the principles of gymnastics, and even the application of the latter to the treatment of disease. The precepts therein inculcated are in accordance with the Chinese maxim: "Perfect thyself; renew daily thy substance; renew perpetually thy vigor."

The "Cong-fou" insists at great length on the necessity of respiratory gymnastics, and endeavors to explain this necessity from physiological reasons. According to this Chinese book, it is exercise which establishes the equilibrium of respiration, and respiration keeps up the proper adjustment in the movements and composition of the blood. "Respiration," adds this ancient hygienic writer, "changes the composition and proportion of the principles of the blood." It is worthy of remark that these statements are in harmony with modern science.

I shall not here reproduce all the details which this book gives relative to movements to be practised. It prescribes three attitudes or postures, and these admit a great number of varieties. Three ways of breathing are indicated,—one by the mouth, another by the nose, the third by the mouth for inspiration and by the nose for expiration. These forced breathing exercises are as much in use to-day as they were forty-five hundred years ago when first prescribed.

We who belong to the Indo-European family are especially interested in knowing what the Hindoo race knew relative to the gymnastic art and its applications. When the white men, the *Pandous*, sixteen centuries before the Christian era, had driven out the black men, the original occupiers of the soil (the *Kourous*), the Vedas appeared,—the sacred books of the nation, supposed to have been a revelation from Brahma. Among

* Dally père, "Cinésiologie ou science du mouvement dans ses rapports avec l'éducation, l'hygiène et la thérapeutique," Paris, 1857; Dally fils, art. "Gymnastique," in "Dictionnaire encycl.," Hillairet, "Enseignement de la gymnastique dans l'Université," 1878; Collineau, "la Gymnastique," Paris, 1884; Chancercel, "Histoire de la gymnastique médicale depuis son origine jusqu'à nos jours" (Thèse de Paris, 1864).

these Vedas there is a book called the "Ayur-Veda, or Science of Life," which is devoted to medicine.

According to the mythical tradition, an ancient sage, Bahradwaja, to remedy the ills and infirmities which afflicted humanity, demanded help of Indra, who kindly granted the prayers of the sage and taught him the precepts of the "Ayur-Veda."

This "Ayur-Veda," the most ancient book of Hindoo medicine, is divided into eight chapters, one of which is devoted to alimentation and to hygiene. These precepts of the "Ayur-Veda" have been reproduced in the work of Susruta, where they may now be seen. You will find also in the "Code of Manou," compiled about 1300 B.C., much valuable information respecting the hygiene of the Hindu nation. You will there observe, as in the "Cong-fou," precepts concerning frictions, massage, ablutions, and rules for breathing.

The sixth book of the "Laws of Manou" says in express terms, "The Sanniasi (devotee), to purify himself, must bathe and hold his breath six times; he effaces his sins by holding his breath." By the side of these religious rules we must also place the dances which were practised at the doors of the temples, and which you will find described in the recent work of Dr. Edmond Dupouy. These dances, performed by Indian priestesses (bayadères), made part of that assemblage of practices to which has been given the name of sacred prostitution.*

From India the practice of gymnastics was carried over to Egypt, and there maintained its sacred and military character. Writers have especially insisted upon the military character of gymnastics, and under the name of *Agonistics* were included a variety of martial feats and dances. The study of the monuments of Egyptian antiquity leaves no doubt as to the development and importance which these dances and these exercises had acquired in the social education of the Egyptians. You will find in the works of Champollion-Figeac, and especially in the treatise which Krause has devoted to this subject, much valuable information respecting these exercises.

We come now to Greece in the day of its glory, and we may also say, to the time of the highest development of gymnastics as applied to the perfecting of the body and to the treatment of divers diseases. Admirers of physi-

cal beauty, of which the ancient statuary has given us immortal examples, the Greeks carried, as far as possible, the application of exercise and of movement to the vigorous and well-proportioned development of the body, and in the education of their youths and in the training of adult life, the efforts of this ancient people had this one end in view, "To put the soul of a sage into the body of an athlete."

The Olympian and Isthmian games, by the almost divine honors bestowed on the conqueror, show us the importance which all Greece assigned to gymnastics. St. John Chrysostom tells us, in fact, that when the athlete Exanetus returned victorious from the Olympian games, his fellow-citizens made a breach in the walls of his native city to give entrance to the three hundred white horses and their chariots which formed the triumphal procession.

We have quite exact data respecting the Grecian gymnastics, and you will permit me to state rapidly the principal facts. The Greeks divided gymnastic exercises into four classes. There were first the natural exercises, racing, leaping, swimming, walking, wrestling; these were called *palestrics*, from *παλαίω*, to wrestle. Then came movements with military arms; this kind of gymnastics was called *oplomachia*; religious dances constituted *orchestrics*; lastly came *medical gymnastics*, which formed an important branch of the art of healing.

The gymnasia where the Greek youths exercised themselves, and where also philosophers gave instruction, were immense and magnificent buildings, where were accumulated the most beautiful specimens of ancient statuary and Attic marble. Athens had four of these great gymnasia,—the Academy, the Lyceum, the Ptolemon, and the Cynosarge, the latter being reserved for the lower classes and for slaves.

There, under the direction of the *gymnasiarchs*, the young men of Greece engaged with enthusiasm in all sorts of physical exercises. Men and women practised gymnastic exercises completely naked, for the Greeks associated the idea of exercise with that of nudity, as the name *gymnastics* (from *γυμνός*, nude) implies. Without doubt, it is to the practice of these exercises, and this habit of performing them naked, that the Greek sculptors were able to find in the gymnasia models of all that we to-day consider as the ideal of physical beauty.

Herodicus, one of the teachers of Hip-

* Dupouy, "La prostitution dans l'antiquité."

pocrates, was the founder of medical gymnastics. Having experienced in his own person the good effects of exercise, in being thereby cured of a disease regarded as incurable, he recommended it for a great variety of affections, and carried to the extreme the precepts of gymnastics.* Thus, to fever patients he ordered a walk from Athens to Eleusis by way of Megaris, and back again without stopping, which represents a distance of thirty-three kilometres, or about eighteen miles, one way; this would make altogether a pretty long walk of sixty-six kilometres for a patient in a febrile condition. Hence it is that his pupil Hippocrates blames Herodicus, and affirms that often persons succumbed to the effects of these forced exercises.

After Herodicus, next in order comes Iccus. While the former was pursuing his vocation at Athens, Iccus was filling the office of medical gymnasiarch at Tarentum. He was the first to conjoin with the exercises to which the athletes were subjected, a special dietary regimen, thus laying the foundations of physiological training.

Disciplined or trained for an exclusive end, veritable products of the gymnasium, the athletic champions of the Olympian or Isthmian games presented but a moderate resistance to the fatigues of hard labor, and especially to those of war, and made but middling soldiers. Hence it is that Hippocrates, who has so well summarized the precepts pertaining to the application of movement and of exercise to the treatment of diseases, protests strongly against the abuses of gymnastics, and his view is summed up in the following aphorism: "It is from the exact proportion between exercise and health that the harmony of the functions arises."

Greek medicine made every way great account of movements and of exercise in the treatment of diseases. Hence Littré, with good reason, considers medical gymnastics as one of the three sources of Greek medicine, the other two being furnished, the one by the precepts of the priests of Æsculapius, the Asclepiades, the other by the teaching of the philosophers, who, as you know, gave the study of medicine a place among the branches of knowledge which they imparted. For a time the Asclepiades had few followers, and almost everybody frequented the gymnasia, where were found together the gymnasiarchs and the philosophers.

You will find in one of the writings of Hippocrates, a passage which well expresses the notion which was held respecting the action

of gymnastics in the treatment of diseases: "The fullers trample their fabrics under their feet, they wring them, they beat them, they wash and scrub them, and toughen them, removing all their impurities, and it is the same with regard to our bodies, and this is the good which we get from the practice of gymnastics."

In passing from the Greeks to the Romans, gymnastic exercises underwent a transformation. It was no longer the supreme end to attain the ideal of physical beauty, but the predominant desire was, on the one hand, to make soldiers; on the other, gladiators. In annexing baths to the gymnasia, an innovation borrowed from the East, the Romans completely modified these establishments, which little by little became places of debauchery, and they thus prepared the people for the ages of decadence and degeneration which followed; and all this notwithstanding the efforts of Antonius Musa, physician to Augustus and of Charmis of Marseille, who founded hydrotherapy, and substituted for vapor-baths and warm baths the usage of cold water. All the physicians of the Roman period (physicians of Greek origin be it understood) taught the utility of exercise in the treatment of diseases, and you will find in the celebrated collection which Oribasius made in A.D. 360 (under the orders of Julian) of all the writers of antiquity who treated of medicine, an entire book devoted to gymnastics; this work has been translated by Daremberg. You will there see the principal indications formulated by the ancients for the application of gymnastics to the treatment of diseases. There are, moreover, some very interesting paragraphs on respiratory gymnastics.

According to a passage of Antyllus, cited by Oribasius, the act of declaiming with a loud voice has for effect to dilate the thorax and augment the respiratory capacity, but such declamation should be prohibited in cases of hæmoptysis.

According to Galen, also cited by Oribasius, exercise is *all movement whose effect is to change the respiration*. The physician of Pergamus also dwells on the importance of all gymnastic exercises, and, furthermore, of frictions, massage, and even of passive movements, which, in his practice, constituted a veritable Swedish movement cure which was applied to the treatment of fevers.

Leaving the fourth century, we find no writers worthy of note till we come to Aetius in the sixth century, Alexander of Tralles and Paul of Ægina in the seventh century, who

reproduce in their compilations almost the entire work of Oribasius. Then thick night fell on all that pertained to the arts and sciences, a night which lasted till Europe, emerging from out the Middle Ages, saw ushered in the dawn of a new period,—the RENAISSANCE.

During this long period, constituting the Dark Ages, which extends from the sixth to the sixteenth century, comprehending a thousand years, the practice of hygienic exercises was not abandoned, and we see it put in use in the training of knights-errant, and while one set of men shut themselves up in cloisters, and there submitted to the rigorous rules of asceticism which were enforced in these places, others, on the other hand, gave themselves up with ardor to physical exercises, and constituted that chivalry which, if it did not create artists and men of science, nevertheless gave the world strong and vigorous men, capable of bearing the heavy accoutrements of war, and an amount of massive and weighty armor such as fills us with astonishment at the present day.

The Arabian school, which alone preserved during this long space of time the traditions of antiquity, added nothing to the practice of the ancients, manifesting rather degeneration than progress, and in the works of Rhazes you will find but a few short passages pertaining to medical gymnastics.

Coming down to the sixteenth century and the Renaissance, we find awakened a zeal for revising and collating the masterpieces of antiquity, of which collections from all sources were made. In this work of research and annotation, due place was given to gymnastics. Thus, Antonio Gazzi, of Padua, in his "Florida Corona" (Floral Crown), which is, he says, "composed of the most beautiful flowers gathered in the fields of Hippocrates and Galen," has not omitted to compile all that has a bearing on hygiene, and in particular, on gymnastics. Lastly, in 1573, at the end of the sixteenth century, appeared the first special treatise on gymnastics, the production of Mercurialis, who was, as Hillairet has well said, the father of modern gymnastics.

But it is not so much in the works of medicine properly so called, or of hygiene, that you will observe precise indications respecting gymnastics. You will find the importance of bodily exercises recognized, and valuable lessons thereon, in the writings of the philosophers, and especially of the great reformers, who endeavored to introduce sage innovations into the education of the youth,

and among these I may mention Rabelais, Martin Luther, and Montaigne.

In his immortal work, Rabelais dwells much on the necessity of gymnastic exercises in the education of his *protégé*, the young Gargantua, and we there find the precepts of the ancients accommodated to the tastes of the period. He insists particularly on the utility of respiratory gymnastics, which he says develop and strengthen the organs and muscles of the thorax.

Luther, the father of the Protestant Reformation, is quite as affirmative on the subject of the necessity of gymnastics for the preservation of the health. Gymnastic exercises, he says, give strong and robust limbs, and promote the health of the whole body. Youths who are interested in them will not be likely to abandon themselves to lazy habits, to debauchery, to strong drink, or to card-playing. Our great philosopher Montaigne has a striking passage in his letter to Diana of Frix, Countess of Gurson, in which he sets forth in a clear manner the importance of making the physical training keep pace with the moral; and I cannot but think, with Dally, that it would be well if the entire passage were printed in large letters on the walls of our schools: "It is not a soul, it is not a body, that you are developing, it is a man—and you are not to treat them as if they were separate, or cultivate the powers of the one without at the same time cultivating those of the other. They should, in fact, be managed like a pair of horses harnessed together."

Such were the views of the reformers of that time, but these precepts bore no fruit in the way of gymnastic institutions, despite the earnest pleading in behalf of a better system of physical training, at a later day, by Rousseau, who, in his "Emile," again urges the necessity of bodily exercises, and compares gymnastics to dancing, then much in vogue, and to the disadvantage of the latter, which he affected to despise.*

I must not omit in this connection to mention the names of Nicolas Audry and Tissot. The phlegmatic dean of the Faculty, sworn adversary of the surgeons, whose thesis bore the strange title: "On the Influence which the Cheerful Demeanor of the Physician and the Obedience of the Patient may have on the Cure of Diseases,"—Nicolas Audry, published

* He says, in plain words, that he would rather skip like a roebuck than dance like some of the performers of the period: "J'en ferai l'émule d'un chevreuil plutôt que d'un danseur de l'Opéra."

in 1741 a treatise in two volumes on "Orthopædics," in which he rightly insists on the importance of movements and of exercise in the treatment of the deformities of early life. Tissot, who was surgeon-general of the light cavalry, published in 1780 a very complete work on gymnastics, which has more or less influenced all subsequent writers on the subject.

Lastly, at the end of the eighteenth century, and coincidently with the appearance of the works above mentioned, gymnastic exercises acquired a permanent place in all public systems of education, and this salutary innovation was due to one who may be regarded as the true founder of modern primary instruction as instituted on a common-sense basis: I refer to Pestalozzi. In this connection I need but refer to one simple, unpretending treatise of this remarkable man, with this naïve title, "How Gertrude taught her Children,"—a book which lays down in a masterly manner the principles of the inductive system of education. Pestalozzi was a Swiss, of the canton of Unterwald, and no place could have been better chosen to serve as the cradle of modern gymnastics. Placed in the centre of Europe, inhabited by a population of mountaineers skilled in exercises of the body, Switzerland adopted with ardor the ideas of Pestalozzi, and there sprang up under the impulse emanating from him, gymnasiums at Stanz, at Berthoud, and at Yverdon, where flocked not only the Swiss youths, but also people from neighboring countries. Gulsmuths, a native of Saxony, became the pupil of Pestalozzi, and carried his method to Germany, while Natchtigall did the same for Denmark, so that at the commencement of this century, three European countries possessed gymnasia,—Switzerland, Germany, and Denmark.

From this time onward, gymnastics became a regular part of scholastic and medical training, and were cultivated in all parts of the world. There are four names in particular which sum up the efforts made in this direction during the first part of the nineteenth century,—Ling, of Sweden; Jahn, of Germany; Clais and Amoros, of France.

Ling, while a student of the University of Upsall, was suffering from retraction of the muscles of one of his arms, which resulted from a wound which he had received in 1801 in a naval battle between the English and Danes. He combated this retraction by fencing, and delighted with the remarkable results which he had obtained, he abandoned

his chair of Scandinavian poetry and mythology, to devote himself specially to the teaching of gymnastics. He originated that aggregate of special exercises to which has been given the name of Swedish gymnastics, and which I shall describe at length in the next lecture, when I come to treat of the exercises of gymnastics.

If with Ling, gymnastics became identified with medicine, and to such an extent that he may be regarded as the founder of modern kinesitherapy, with Jahn it took another turn, and became associated with patriotism and military prestige. Jahn desired that gymnastics should help on the triumph of the German ideal, and took for his device: "Liberty, autonomy, our country's glory!"

As for France, it is to Clais and Amoros that we owe the establishment of the first gymnasia. Clais was born in Berne in 1780. He became professor at the academy of this city, then came to France, passed over into England, where he sojourned awhile, then came back to France again, carrying everywhere his precepts of gymnastics. It is especially in a report to the Society of Medicine of Paris that you will find the clearest indications as to what his teaching of gymnastics consisted in.

Amoros was a Spaniard, who, for political reasons, was exiled from his native country. He made France his home, and devoted his life to the propagation of gymnastics. I myself when a boy attended the exercises of Colonel Amoros. These exercises took place in an immense gymnasium, which he had built in the Champs Elysées, in the street which now bears the name of Jean Gougon. Thither Tuesdays and Sundays the pupils of the different boarding-schools were conducted, and when the exercises by section were finished, we were all marshalled together into an apartment, where Colonel Amoros taught us to perform, while singing, those exercises in concert which constituted more particularly the gymnastic system of Amoros.

From the time of Clais and Amoros, gymnastics underwent rapid development in France, and became obligatory in the primary schools, while in the army, the soldiers were taught to execute those concert movements, and those movements tending to give suppleness to the limbs, which so fit them for their special calling.

Among the numerous masters of gymnastics, there is one whom I ought to signalize, especially since all mention of his name is omitted in the otherwise very complete thesis

of Chancerel; I allude to Napoleon Laisné. He was the first to teach gymnastics in the hospitals of children, and under the direction of Blache and of Bouvier, he applied gymnastic exercises in our hospitals to the treatment of convulsive disorders, such as chorea; and to-day, despite his great age, Laisné has not ceased personally to teach and to direct the teaching of gymnastics in our hospitals and schools.

Before setting forth the various methods and their application to therapeutics, I desire to devote the rest of this lecture to a rapid survey of the physiological action of gymnastic exercises. It is on these effects that we base the applications of medical gymnastics.

Gymnastics act first on the circulation and respiration. The effect on the respiration is, perhaps, far the most important, and Dally has emphasized this point; and in this connection I need only recall to your minds the importance which the ancients attached to the influence of exercise on respiration.

In a general way, gymnastic exercises augment considerably the chest capacity. You can judge of the increase of the amplitude of the chest by the use of registering apparatus to measure the respiratory movements.

In a work written conjointly by Chassagne and Dally* at the Military School of Gymnastics of Joinville-le-Pont, these authorities have shown that of four hundred and one individuals subjected to gymnastic exercises for five months, in three hundred and seven (or seventy-six per cent.), the bi-mammary circumference of the thorax had increased by an average of two and one-half centimetres. In Germany, Dr. Abel obtained similar results, seventy-five per cent. of individuals practising gymnastics having experienced an augmentation of the thorax.

Another mode of mensuration consists in applying to the thorax the process employed in craniometry; this is Fourmantin's method. Under the name of *thoracic index*, he gives the centesimal relation of the transverse diameter of the thorax to its antero-posterior diameter, a relation expressed in the following

formula: $\frac{DT}{100} \times DAP$.

The flatter the chest, the higher will be the index figure, and the rounder the chest, the less will be the figure, for flattening of the chest corresponds to low development and low respiratory capacity. In phthisical pa-

tients, for instance, the thoracic index varies between 135 and 152, while in individuals possessing a sufficient and normal respiratory capacity this index is but 128. Gymnastic exercises tend to lower the thoracic index.

But the instrument which most clearly expresses the amplitude of the respiratory movements is the pneumograph, which enables us, as you may now see, perfectly to enregister the amount of respiratory expansion.

In the interesting researches made by Marey,† "On the Influence of Movement on the Respiration and Circulation," he obtained, by the aid of the pneumograph, tracings which I here place before you, and which show you, better than anything else can do, that under the influence of gymnastic exercises the amplitude of the thoracic movements may be doubled.

This augmentation in the capacity of the thorax has several consequences. First of all, it enables a greater quantity of blood to come in contact with the air of respiration, and this increases the combustions of the economy. It also enables a greater quantity of air to penetrate the lungs. This latter is of capital importance, for this augmentation of the respiratory capacity opposes that breathlessness (*i.e.*, that marked increase of respiratory movements) characteristic of active exercise. Edward Smith has, in fact, shown us, that if we represent by the figure 1 the quantity of air which hourly penetrates the lungs (five hundred and forty litres) in an individual lying down, this figure will augment in the following proportions, if the individual devotes himself to the exercises below specified:

Standing.....	1.33
Moderate walking	1.90
Rapid walking.....	4.76
Horseback-riding	2.20
" galloping.	3.16
" trotting	4.05
Swimming	4.31
Rapid running.....	7.00

In order to cause a sufficiently large quantity of air to penetrate the lungs during the corporeal exercises which I have just enumerated, such an augmentation of the ordinary movements is required, that breathlessness is rapidly produced in persons who are not habituated to these gymnastic exercises. But, as I have just told you, gymnastics, by augmenting the respiratory capacity, enable the individual to breathe in more air with each respiration,

* Chassagne and Dally, "Influence of Gymnastics on the Development of Man," 1881.

† Marey, *Acad. des Sciences*, July 10, 1881.

and thus lessen the number of respirations and avoid getting out of breath.

In the tracings which I have just shown you, you saw that the pulse was also indicated, and that exercise augments both the number of the pulsations and their amplitude. This influence of gymnastics on the circulation is quite as important as their influence on the respiration. The greater activity of the circulation results from two causes,—first, the muscular contraction; second, the increase of pulmonary capacity.

Muscular contraction energizes the venous circulation. We have a proof of this in the operation of blood-letting, when, in order to obtain a freer flow of blood from the open vein, we tell the patient to execute with the hand movements which bring into play the muscles of the forearm. The enhanced activity of the pulsations of the heart is also due to the fact that the pulmonary capacity being augmented, the demand for venous blood by the lungs is greater. More blood comes to the right ventricle, which causes more to flow into the left ventricle, so that the venous circulation and the arterial circulation are augmented. As to the action on the heart-muscle, I shall take that up in the next lecture, when I come to the treatment of diseases of the heart by gymnastics.

In the muscles the influence is more direct. Forcible contractions give rise, in the muscular substance, to physical and chemical phenomena which augment the nutritive exchanges, and cause the muscular bundles to become thicker and firmer. I have no need to give you in this place direct proofs of this fact. Such physiological proofs abound, and you have only to confine one limb in splints and exercise the other, to have a demonstration of the atrophy which attends the bandaged limb, and the increased development which marks the limb that is exercised.

These exercises not only promote the development of the muscles, they act also favorably on the nervous system. In fact, every co-ordinated muscular movement entails a nervous expenditure, and without going as far as DuBois-Reymond (*Revue Scientifique*, 1880), who affirms that the exercises of the body are rather exercises of the central nervous system, than muscular exercises, one may truly say that gymnastics tend to restore the equilibrium between the functions of the brain and those of the spinal cord.

Gymnastics act not only on the respiration, circulation, musculation, and innervation, they also promote secretion and excretion.

All movements which are somewhat prolonged provoke the production of sweat, which is one channel of elimination for urea and uric acid. I have seen the perspiratory secretion augment by an hour's exercise to six hundred grammes, and even in some subjects attain the figure of fifteen hundred grammes. This is, you know, a channel of excretion which is vicarious with the renal emunctory, and which we may utilize to great advantage in therapeutics.

If I were to sum up in one sentence the physiological action of gymnastics and bodily exercise, I would say that they promote and invigorate nutrition. I have just showed you that by the enhanced energy of the circulation, and the increase of the respiratory capacity, a greater quantity of venous blood comes in contact with the air, and that this energizes the phenomena of combustion. I have shown you, moreover, that by exercise the muscular interchanges are promoted.

This augmentation in the muscular and respiratory combustions entails an augmentation of heat, and in this connection we may properly refer to the careful experiments of Rouhet and of François Franck.* These experimenters have demonstrated that muscular exercises augment the central temperature, but that, owing, on the one hand, to the production of sweating, and, on the other, to the greater quantity of venous blood brought in contact with the air of respiration, and producing a veritable pulmonary sudation, equilibrium is established between the external temperature, which falls, and the temperature of the deep parts, which rises.

But this is but one aspect of the question. Last year I showed you the important rôle of the cell in nutrition. Under the influence of gymnastics, the activity of the cellular functions is enhanced and regulated, the intracellular combustions are energized, the leucomanes, those toxic alkaloids which the organic cell constantly fabricates, augment in quantity, and are more actively eliminated; and from all these circumstances it results that fatty substances and waste extractives are burned, cell repair is promoted, and equilibrium is effected between the cells of the brain and spinal cord; in a word, general nutrition is expedited.

The digestive functions do not remain indifferent to this nutritive gain, and they are

* Rouhet, "Experimental Researches on the Physiological Effects of Gymnastics and of Training," pp. 36 and 45. Paris, 1881.

beneficially influenced in two ways,—first by the contractions of the diaphragm and abdominal muscles, which invigorate the abdominal and hepatic circulation, and indirectly by the augmentation of the combustions of the economy; and it is a trite thing to say that exercise increases the appetite. Hence Chomel was right in affirming that one digests with his legs as well as with his stomach.

It must be borne in mind that to obtain this enhanced activity of digestion, it will not do to undertake violent exercise immediately after the ingestion of a hearty meal. You all remember the fact, so frequently mentioned in treatises on physiology, that when you take two dogs after a full meal, and shut up one of them in its kennel, and cause the other to engage in violent running, digestion is more advanced (other things being equal) in the dog which is kept at rest than in the one which is subjected to active exercise.

This general influence on nutrition is represented by palpable signs, and this is the case even in adult men,—augmentation of muscular force and augmentation of weight. In a table which you will find in the work of Chassagne and Dally, and which I here place before you, you see indicated the augmentation in kilogrammes noticed in the pupils of the Military School of Joinville le Pont:

	Augmenta- tion in kilo- grammes.	Percent- age of pupils.
Lifting force.....	28.00	86
Force of flexion of the forearm on the arm.....	3.14	63
Force of flexion of the fingers on the palm of the hand.....	9.75	81
Force of the extended arm.....	2.41	74
Force in carrying loads.....	11.52	66
Force of progression or of traction....	9.81	65
Force of the triceps contraction, or of ankle contraction.....	10.08	75

As to the augmentation of weight, it is far from being constant under the influence of gymnastic exercises. Hence among these same pupils, trained in gymnastics, thirty-four per cent. only, at the end of six months of training, had increased in weight by an average of 1.14 kilogrammes; the remaining sixty-six per cent. had either not gained at all, or had lost in weight, and this is easily explained. Gymnastic exercise, by favoring the combustion of fats, and by augmenting the organic combustions generally, by invigorating the cellular nutrition, is a powerful means for promoting emaciation, of which we avail ourselves in the treatment of obesity. Hence it is that gymnastics have the effect to make

corpulent persons grow lean, and to lose in weight, while both muscular development and muscular force are augmented.

In individuals who have no accumulation of fat in the cellular tissue, corporeal exercises, on the contrary, will have the effect by augmenting these muscles to increase their weight. But to obtain these effects it will not do to carry the exercise too far, for, if practised to excess, the individual will grow lean and become feeble, and offer all the symptoms included under the name of *overstrain* (*surmenage*).

The effects of overwork have been well studied in animals, and, in particular, in horses. When you subject animals to excessive toil, you see them grow lean and feeble, despite abundant feeding, and they easily become a prey to epizootic diseases. It is the same with man, for gymnastic exercises, carried to too great a length, weaken and prostrate, and render the person an easy victim to tuberculosis.

What I say, gentlemen, has been known from remote antiquity, and the Father of medicine, while recognizing the utility of physical exercises, protests against their excess. He shows that athletes in particular stand the fatigues of war with difficulty, and fall a prey more readily than others to diseases; in a word, they make poor soldiers.

But if for the adult age gymnastics when pressed too far are hurtful, for children a reasonable amount of such exercises is in every way advantageous. In the early period of life the child is in the plastic, formative stage of its existence, and its constitution readily takes the bent which its physical education imparts. In giving the child a judicious gymnastic training you develop the skeleton and the muscular tissue, you augment the capacity of the thorax, you invigorate the circulation, you equilibrate the functions of the nervous system, you favor nutrition; in a word, you develop all that pertains to robust manhood.

Therefore there is general agreement in giving gymnastics an increasingly prominent place in the education of boys and girls. But this is a point to which our civilization has long been tending, and I have already said sufficient about its importance. I pass on now to a consideration of the applications of gymnastics to the treatment of diseases, a subject which I shall take up in the next lecture.

CRITICAL OBSERVATIONS AND EXPERIMENTAL STUDIES ON THE INFLUENCE OF PHARMACOLOGICAL AGENTS ON PERIPHERAL VESSELS.

BY PROF. R. KOBERT.*

PART II.

IN the first part of this work (THERAPEUTIC GAZETTE, January 15 and February 15) I have given a review of all the investigations previously made by the authors of other countries upon the circulation in the organs of warm-blooded animals, from the standpoint of its bearing upon the study of pharmacology.

In these papers I have cited Alexander Schmidt, of Dorpat, as the first writer who had made and reported experiments upon organs removed from the body with various drugs. Historically, however, this is not correct, for Friedrich Bidder has informed me that in 1862, five years before Schmidt, he had made such experiments, assisted by his son, Ernst Bidder, upon kidneys removed from the body.†

Similar experiments were made in 1849 by Loebell.‡ After this historic digression I will commence my present paper.

In my paper in the THERAPEUTIC GAZETTE of February 15, 1887, p. 90, I said that I would speak later of the drugs of the digitalis group, which possess other properties than those already recognized.

The great importance which the digitalis group possess in therapeutics has led me to review all my previous experiments with new apparatus before studying other allied substances, and I have been assisted by Dr. Hermann Thomson, assistant in the clinic of gynecology, who has reported his experiments upon the working of digitalis upon the vessels, and also the influence of drugs which I had not previously studied, in his inaugural dissertation,§ and also in the Russian journal *Wratsch*. I append on page 371 a table of substances, which in all organs examined and under all circumstances cause blood-vessels to contract.

* Chief of the Pharmacological Laboratory at Dorpat, Russia.

† Ernst Bidder, "Contribution to the Study of the Functions of the Kidney," *Inaugural Dissertation*, Dorpat, 1862. With a lithographic illustration.

‡ Loebell, "De Conditionibus, Quietis Secretiones in Glandulis Perficuntur," Marburg, 1849.

§ "Upon the Influence upon Peripheral Vessels of Pharmacological Agents," *Inaug. Dissert.*, Dorpat, 1887, 106 pages; with a lithographic plate describing the apparatus used.

This table shows that barium chloride has a marked effect in contracting the blood-vessels. In contrast to all the substances of the digitalis groups this agent produces no effect upon the heart, nor does it further the development of bacteria and also decomposition products when kept for some time in watery solution. I can, therefore, recommend barium chloride as an agent to produce the effect of digitalis locally upon a limb, for example, where dilated blood-vessels exist. The best application for dilated cutaneous veins (for example, on the legs) is the following:

R Barii chloridi, gr. xxx;

Dissolve in distilled water, and mix thoroughly

Lanolini, ʒiij¼;

Olei amygdalarum dulc., ℥lxxv. M.

F. Unguentum.

Sig.—Three times daily, with friction, whenever dilated blue veins shine through the skin.

Barium chloride can be also used in the place of substances of the digitalis group in cases of heart-disease where help is demanded so soon that remedies given internally are not available.¶ We can then use

R Sol. barii chloridi, 1 to 100.

Sig.—⅓ to ½ the contents of a hypodermic syringe should be given at a dose for heart-lesions with deficient compensation.

We know that substances of the digitalis group have an influence upon the gastrointestinal tract to such an extent that vomiting and purging may be excited by these drugs, not only when given by the mouth, but also when given subcutaneously. Barium chloride and all the soluble salts of barium have an effect upon the intestine, in that they are excreted through the intestines after being taken by the mouth, and in large doses may cause diarrhoea. It is not yet known that the digitalis group are excreted through the intestines, but the analogy with the barium salts suggests such a process. For the physician the fact of practical importance remains that when administering barium chloride, if diarrhoea supervenes, the drug should be discontinued.

Barium chloride has an influence, not only upon the vessels and intestinal tract, but also upon the heart, analogous to the effect of digitalin. Experiments upon frogs show that after injection of a small quantity of barium salt

¶ At least until we possess some other substance of the digitalis group suitable for subcutaneous injection, and better in effect than those now in our hands. *As yet we have not one such substance.*

TABLE I.

Table of those Substances of the Digitalin Group which Contract the Vessels of all Organs.

I.	II.	III.	IV.	V.	VI.	VII.	VIII.	IX.
No. of experiment.	Kind of animal.	Organ.	Pharmacological agent.	Per 1000 contents of blood in IV.	Duration of action.	Changes of velocity of outflow in p.p. cent.	Transfused absolute quantity of IV. in grammes.	Special remarks.
1	Ox.	Kidney.	Chloride of barium.	0.40	1	— 11	40	Organs and blood used 18 hours after death of animal, kept on ice. After the contraction, in the next minute, a well-marked compensatory widening followed.
2	Ox.	Kidney.	Chloride of barium.	2.00	1	— 20	190	
3	Ox.	Kidney.	Chloride of barium.	2.00	1	— 10	200	
4	Sheep.	Spleen.	Chloride of barium.	2.00	3	— 8	180

the heart ceases to beat in systole precisely as after the use of digitalis. Striped muscle furnishes, however, an excellent differential point between barium salts and digitalis. All drugs of the digitalis group, when given in small medicinal doses, produce a lessening of the contractile power of muscle, so that patients who are taking scilla, convallaria, adonis, digitalis, strophanthus, etc., after a short time feel their muscular power greatly lessened in spite of improved cardiac rhythm, lessened dropsy, and stronger pulse. Under the influence of barium salts, on the contrary, the extent and degree of muscular contraction (independently of nervous influence) are increased, as Brunton* has found, and I bear added witness to the fact.

Barium in this particular resembles veratrine, which has a similar effect, but in much greater degree, but is so poisonous that we cannot use it as a therapeutic agent.

It was, however, of interest to Thomson and me to know that strontium exercised a like contractile force upon the blood-vessels, and the table shows its effects to be analogous to that of barium.

The table shows also the vaso-motor effect of physostigmine and veratrine, as was indicated in my former experiments; this is also true of antiarine and sabadilline.

Of the substitutes for digitalis in practical use I have examined helleborine, soillaine, convallamarine, erythrophleine, oleandrine, and apocynine, and found them possessed of power to contract blood-vessels. We have also found the same power in helleboreine, soillaine, con-

vallamarine, and erythrophleine, and we include, as of similar effect, adonidine and strophanthine. All of these drugs have the effect of digitalin of Schmiedeberg,—i.e., they narrow the blood-vessels of all organs which were examined in the course of my investigations; also the kidneys. To explain what is meant by "digitalin of Schmiedeberg," I will say that under this name I understand that body which my honored teacher, O. Schmiedeberg, has described in the third volume of his *Archives*, page 27, and which contains sixty per cent. oxygen and eight per cent. nitrogen. It is absolutely insoluble in water, and is contained in the plants of the digitalis family in very small amounts, and is therefore very expensive. The greater portion of the proportions of digitalis in the market (French, English, and German) contain a very small amount or none at all. This point would not be mentioned if Lafon, a French author, in the *Bullet. de l'Académie de Médecine de Paris*, 1886, No. 12, p. 528, had not published an incorrect explanation regarding Schmiedeberg's researches, although he had been in the institute of the professor. Against his errors Merck, of Darmstadt, published a protest, which was given in the THERAPEUTIC GAZETTE, 1886, p. 768. The statements of Merck and Schmiedeberg agree exactly.

In marked contrast to all the substances previously described are two others, digitoxin† and digitalein,‡ of which I have specimens from Schmiedeberg himself, and which exercise a dilating, and not contracting, power upon the vessels of the kidneys.

* *Transactions of the Royal Society*, i., 1884, p. 222: "Action of Salts of the Alkaline Group on Muscle and Nerve."

† Described by Schmiedeberg in Bd. iii. p. 35, of his *Archives* (Leipzig, Vogel, 1875).

‡ Described as above.

109	Ox.	Kidney.	Digitoxin.	0.032	4	+ 20	6.0	Later compensatory contraction. After poisoning a compensatory contraction of —20 per cent. Very pronounced compensatory contraction. Later compensatory contraction. Later a brief compensatory contraction.
110	Sheep.	Kidney.	Digitalein.	0.016	2	+ 12	1.1	
111	Sheep.	Kidney.	Digitalein.	0.010	4	+ 14	1.2	
112	Sheep.	Kidney.	Digitalein.	0.016	4	+ 27	1.6	
113	Sheep.	Kidney.	Digitalein.	0.016	3	+ 28	2.0	
114	Sheep.	Kidney.	Digitalein.	0.009	3	+ 17	1.3	
115	Hog.	Kidney.	Digitalein.	0.020	2	+ 66	1.1	
116	Hog.	Kidney.	Digitalein.	0.020	2	+ 88	1.9	
117	Dog.	Kidney.	Digitalein.	0.333	4	+ 24	20.0	
118	Dog.	Kidney.	0.313	2	+ 50	10.0	
119	Dog.	Kidney.	Digitalein.	0.333	4	+ 50	10.0	Central nervous system preserved.
120	Ox.	Kidney.	Digitalein.	0.166	7	+ 30	18.0	
121	Ox.	Kidney.	Digitalein.	0.083	3	+ 13	11.0	
122	Frog.	The whole body.	Digitalein.	0.100	2	+ 25	2.8	
123	Frog.	The whole body.	Digitalein.	0.040	3	+ 5	1.0	
124	Frog.	The whole body.	Digitalein.	0.040	4	+ 16	0.5	

From a comparison of these two tables it is evident that *the effect of digitoxin and digitalein differs from that of the others of the digitalis group in that in the doses in which we have reason to expect by analogy that these drugs would contract the vessels of the kidneys they not only do not contract but dilate them*,* while, like digitalin, helleboreine, adonidine, convallamareine, etc., in all other organs of the body they contract the blood-vessels.

Thomas Fraser has observed that strophanthine has not this power of causing contraction. I am not prepared to admit this; more observations must be made.

I believe that strophanthine, which I have myself prepared from genuine seeds, has an effect identical with digitalin, helleboreine, barium chloride, etc.,—namely, to contract the blood-vessels of all the organs of the body.

If the question be raised what significance in therapeutics the remarkable effects of these two† substances possess, we must reply that in cases where a prolonged and energetic secre-

tion by the kidneys is necessary in a patient suffering from hydrops, the result of impeded circulation, the contraction of all the blood-vessels of the periphery is of the greatest practical importance, so that the peripheral blood-channels may be narrowed and the rapidity of the circulation be enhanced through the increased functional capability of the heart (which has been clearly demonstrated by F. Williams,† of Boston), and as a result of the increased rapidity and activity of the circulation, both in the body at large and in the kidneys, the secretion of urine will be increased.

It is evident, however, that when in the kidney itself the blood-vessels are not only not contracted but slightly dilated, the secretion of urine will be still more abundant, inasmuch as the quantity of urine produced depends not only upon the rapidity of the renal circulation, but also upon the volume of blood present in the kidneys. The greater the volume of blood present, at least in the glomeruli and convoluted tubules, the greater the amount of urine which can be secreted. It is therefore evident that by means of the agent which produces contraction of the blood-vessels of the entire body the secretion of urine can be favorably influenced, until by

* After the use of very large doses it happens, as the tables show, that contraction follows the first effect, but this proves the more plainly that the previous dilatation was not an accident, but a result of the drug.

† Two other substances of this group, digitonin and digitin, I found to be without influence on the blood-vessels.

the removal of blood from the periphery the local anæmia of the kidneys can be remedied. While the action of the drug increases, the secretion of urine will lessen rather than continue to increase.

By the use of digitalis, in which, in addition to a substance which contracts all the vessels (digitalin), there are two others in considerable quantities which dilate the vessels (digitoxin and digitalein), we shall produce in a patient a continuous diuresis; for too great anæmia of the kidneys to permit of secretion can never occur. For these reasons are the leaves of digitalis purpurea an agent which through none of the many other vaso-motor remedies can be supplanted, for we are as yet ignorant of other remedies which act like digitoxin and digitalein. The importance of my statement, that digitalis medication has no substitute, every practitioner will admit. The substitution for digitalis of adonis, convallaria, etc., is not because digitalis does not affect the heart properly, but because digitalis often causes vomiting and purging in certain patients in whom the other drugs, adonis, convallaria, strophanthus, etc., do not produce such results. I have recommended barium chloride, not because it acts more powerfully than digitalis, but because it is cheap, is easily and persistently soluble, and produces no irritation when given subcutaneously.

What form of digitalis shall be employed? Most commonly preferred is the infusion. This naturally contains only those substances soluble in water. Of the three important active principles, as digitalein, a drug which produces dilatation of the vessels of the kidneys, is soluble in alcohol, it is contained in the tincture and alcoholic extract. The other constituents, digitoxin and digitalin, are also soluble in alcohol; in alcoholic preparations, as well as in the leaves themselves, we obtain the three important active principles.

In fluid extracts digitoxin is precipitated as an insoluble powder. Acetum digitalis (vinegar of digitalis) approaches the infusion most closely in regard to its contents. It is very desirable that fresh, well-dried leaves be used. When the leaves are imperfectly dried a species of fermentation may occur which may decompose the three essential components of the drug, for digitalin and digitalein are, like all glucosides, decomposable through foreign matter and fermentation. Digitoxin is, however, not a glucoside, but decomposes as easily and under the same circumstances as the others. The result of the decomposition of digitalis is not a substance producing

the desired effects upon the heart, but a resin, digitaliresin (from digitalein and digitalin) and toxiresin (from digitoxin). The effect of these bodies is a violent irritation of the convulsive centres of the brain; severe convulsions may also occur, as in poisoning with picrotoxine or cicuta verosa. Whenever the usual effects of digitalis are wanting, or instead cramps occur, we are safe in thinking that the preparation used was a poor one. The decomposition of digitalis may occur not only in the leaves, but also in infusions and solutions of digitalin and digitalein. As Tardieu* says, "The pure digitalin when suspended in water or dissolved undergoes decomposition in a short time, whereby the bitter taste is altered and, as an indication of a radical change in the constitution of the drug, gases form." Among my patients I have very often seen decomposition in preparations of digitalis which had stood two days in a room. This happens from the mixing of digitalis tincture with syrup or watery solution. The practice prevalent in America of not preparing the drug from the leaves when desired, but of using a concentrated infusion, explains the frequent disappointment in its use.

Post-mortem examinations in cases of poisoning by digitalis are reported, but in one case, observed by Cloetta,† was the distribution of the blood the one important phenomenon observed, and the vessels of the kidneys were found not only not contracted, but dilated. Such a post-mortem appearance is quite unintelligible, save in the light of our experiments on digitalein and digitoxin, for which it furnishes an excellent illustration.

ON LOCAL APPLICATIONS TO THE PROSTATE GLAND;

PARTICULARLY IN REFERENCE TO IMPOTENCY AND URINARY TROUBLES ARISING FROM DISEASE OF THAT ORGAN.

BY T. WILLIAMS, M.D., MILWAUKEE, WIS.

THERE are certain diseases of the prostate gland invested with a peculiar interest to all men, laymen as well as professional, owing to the fact that they are the frequent and often unsuspected source of

* Ambrose Tardieu, "Die Vergiftungen Autorisirt." German edition. Erlangen, 1868. Enke, p. 361.

† Cloetta, "Lehrbuch der Arzneimittellehre," 1883, II. Aufl., p. 217.

urinary troubles, as well as partial or complete sexual impotence in the male. The results of Sir Henry Thompson's researches on this subject, as given in his "Clinical Lectures on Diseases of the Urinary Organs," were that *one-third* of all men over fifty-five have some enlargement of the prostate. Enlargement of the prostate, in fact, is a disease almost peculiar to middle and advanced life, between fifty and sixty; but chronic irritability and inflammation are much more frequently met with between the ages of twenty-five and fifty.

The points of special clinical importance in reference to the anatomy of the prostate are, that when the finger is introduced into the rectum the healthy prostate is felt in the median line as a body about one and one-half inches long, and as broad as it is long, about one and one-half inches from the anus. The vesiculæ seminales lie beyond it, and the vasa efferentia, which convey the seminal fluid, open into that part of the urethra surrounded by the prostate. In all chronic urinary troubles the practitioner should not fail to make a digital examination of the prostate gland, as it will often yield information without which he could not successfully treat the affection.

The object of this paper being to call attention to the great value of local applications to the prostate, it is not proposed to deal fully with its various diseases. I shall, therefore, speak only of those to which this method of treatment is particularly applicable.

I wish to remark in the outset that the *remote* origin of more than one-half the cases of prostatic disease treated by me has been a previous neglected or improperly treated gonorrhœa. The patient may have had the gonorrhœa twenty or thirty years before that laid the foundation, or planted the predisposing cause, of the existing disease. In fact, I believe this also to be the most prolific source of generative weakness in middle life, as the urethra never seems to regain its virgin condition after a case of prolonged gonorrhœa.

HYPERTROPHY OF THE PROSTATE GLAND.

Chronic enlargement of the prostate may be a simple increase in the size of the gland from previous congestions due to frequent or long-continued sexual excitement, or previous inflammation; it may arise from scrofulous or tubercular deposits, from calcareous deposits in its substance, and finally from a new growth caused by an increased flow of blood to the parts. Each of these forms of enlarge-

ment is denoted by certain characteristics which usually enable us to diagnosticate them accurately. The degree of trouble arising from enlarged prostate depends very much upon its character. Thus, the lateral lobes may be greatly enlarged without causing much inconvenience for a long time; but if the middle lobe, forming the floor of the prostatic portion of the urethra, or that portion next to the bladder, is only slightly enlarged, difficulty in micturition is sure to follow. Thus, a simple hypertrophy, which usually affects the lateral lobes, may reach enormous proportions without giving rise to any particular symptoms; while, on the other hand, an enlargement of the middle lobe, which can scarcely be detected by the finger, may cause the most distressing trouble.

The symptoms which indicate enlargement are: difficulty in emptying the bladder, the urine escaping in driblets; there is a frequent desire to pass water, especially at nights and mornings; the character of the urine is usually unchanged, and there may be slight pain before passing it, but usually none afterwards. These are the early or premonitory signs of hypertrophy, and unless relieved increase in severity as the enlargement progresses. The patient reaches a stage where he finds it difficult to hold the water; the desire to pass it is imperative, and must be immediately attended to. This condition is produced by over-distention of the bladder, in which the urine accumulates on account of that viscus not being entirely emptied. From the same cause cystitis, or inflammation of the bladder, is liable to occur, and not only the bladder itself, but also the ureters, which convey the urine from the kidneys to the bladder, become dilated; and this in turn produces inflammation of the kidneys, winding up with Bright's disease.

Those suffering from chronic hypertrophy are liable to occasional attacks of *congestion of the prostate*. Congestion usually comes on suddenly, as a result of some indiscretion in diet or drinking, exposure to cold, or other apparently trivial cause. There is complete retention of urine, accompanied by bloody urine, an increased temperature, quick pulse, and more or less pain and uneasiness in the region of the bladder. If the urine is not speedily evacuated through the catheter, putrefaction ensues, the tongue becomes dry and covered with a brown coat, the pulse becomes faster and weaker, and the patient sinks into a typhoid condition, which may end fatally. Old men are more liable to these

attacks than young men. It is of the utmost importance to prevent putrefaction of the urine, by antiseptic treatment and catheterization, as this is the most frequent cause of death in such cases.

In the treatment of hypertrophy of the prostate, as Dr. Godlee says, "it is only necessary here to give two words of warning. First, that most of the evils resulting from this condition depend upon the fact *that the bladder is never emptied*; it is essential, therefore, that the patient's powers in this respect should be ascertained without delay by catheterization, and if it be discovered that a certain amount of residual urine remains, he should be taught to pass the instrument himself, and directed to do so at least once a day. Secondly, cystitis has often been caused by setting up putrefaction of the urine by a catheter not surgically clean; the simple precaution of lubricating it with carbolized oil prevents with certainty this catastrophe."

The general treatment, including the proper regulation of the patient's diet and habits, will suggest itself to every well-informed physician, and would be foreign to the scope of this paper. My object is to point out the peculiar advantages of *local applications to the prostate* with a view of effecting a radical cure. These advantages can scarcely be overestimated, as by the judicious employment of the proper remedies in this way there is but little question that Bright's disease and other complications which cut short many valuable lives may be averted. It is a well-known fact that the late Napoleon III. fell a victim to prostatic disease, originating many years previously in imprudent excesses of various kinds. Although (as in his case) the immediate cause of death may be some disease of the bladder, or a stone necessitating cutting, or, as in others, kidney-disease, these affections may be traced back to what was at first an apparently insignificant urinary trouble, arising from enlargement of the middle lobe of the prostate, which would have yielded readily to the proper local applications made directly to the prostate urethra.

The nature of these applications and the mode of making them will be referred to in connection with the treatment of chronic inflammation of the prostate. In all cases the local treatment should be combined and used in conjunction with such general treatment as the individual case may seem to require. I will only remark here that great relief and benefit will be experienced from the use of suppositories, properly medicated, and used

per rectum, as the suppository, when introduced, lies adjacent to the prostate gland, and the iodinated or other alterative ingredients with which it is medicated thus readily reach the gland, and supplement the applications made through the urethra. I have obtained excellent results from rectal suppositories of cocoa butter medicated with potas. iod., belladonna, iodoform, and hydrarg. pernit., in proper proportions, one being introduced every night at bedtime, in connection with the local applications.

CHRONIC PROSTATITIS AND ITS VARIOUS COMPLICATIONS.

Chronic Prostatitis, or chronic inflammation of the prostate gland, is one of the most frequent causes of urinary and sexual trouble met with in men between the ages of twenty-five and fifty. Its symptoms resemble those of stone in the bladder so closely that the busy or inattentive practitioner, who has paid no especial attention to the subject, is very liable to mistake the one for the other. These symptoms are: a frequent desire to urinate, with a feeling of weight and heat in the perineum, and a pain extending the whole length of the passage to the tip of the penis.

At times a few drops of blood will follow the water, and generally the patient suffers from frequent nocturnal emissions. The urine is cloudy, and deposits a muco-purulent mass after standing awhile. A rectal examination shows the prostate tender to the touch, and more or less enlarged. It is frequently met with in young and middle-aged men, as a sequel of a prolonged gonorrhœa which has involved the prostatic portion of the urethra. It is not an affection that yields very readily to any method of treatment, and in many cases which have come under my care it had gradually subsided into a mild but persistent chronic form, in which but little enlargement or tenderness of the prostate remained, but in which the gland had taken on a state of hyperæsthesia, and was engorged and irritable. In this condition there is always more or less complaint in regard to the urine, which feels hot, with a slight smarting or stinging sensation after passing; there is often a feeling as if the bladder was not entirely evacuated, which is true, as a very slight enlargement of the floor or middle portion of the gland, as previously remarked, interferes with the complete emptying of the bladder, and causes the last drops to dribble away after the stream of urine has ceased. This symptom is one

which should not be neglected by the practitioner; although it does not indicate that degree of enlargement which causes retention of urine in middle-aged and old men, it is the commencement of chronic hypertrophy, and will eventually lead to it unless relieved.

A still more frequent symptom of hyperæsthesia of the prostate is the oozing out of a thin, transparent discharge, which is increased by any sexual excitement. This discharge, mostly composed of prostatic mucus, is not only very annoying but often alarms the patient, who mistakes it for semen. Seminal fluid, it is true, may be mixed with it, and often is, when the individual has experienced prolonged sexual excitement, or gone to any excess of this kind; but it is a mistake to suppose that the entire discharge is spermatic. The form of excitement referred to above, more especially if it has been unattended by gratification, is, according to my own observations, one of the principal causes of chronic hyperæsthesia of the prostate. We can readily understand how this can be when we consider that always during erotic excitement the prostate gland becomes congested with blood; the copious plexus of veins which surround it communicate freely with those of the vesiculæ seminales, penis, and testicles, and connect not only with the systemic, but also with the portal circulation. In fact, in those who give way to erotic ideas, the prostate is kept congested, although there may be no erection of the penis. The symptoms referred to are always aggravated by exercise, and in cases following chronic gonorrhœa the discharge assumes a gleety character; only a drop may be detected in the morning, but the quantity may be so increased after any excess as to resemble a regular case of gonorrhœa.

In young men, especially those of nervous and excitable temperaments, the most alarming of these symptoms is true spermatorrhœa, with frequent nocturnal emissions and seminal losses in the urine and at stool. In many cases which have come under my treatment these debilitating losses occurred nightly, and sometimes even two and three times during the night, in consequence of the reflex action of the prostatic irritation upon the vesiculæ seminales. So great does the dread of these repeated emissions become that young men have told me that they actually felt reluctant to go to bed. Neither the antaphrodisiacs nor the nerve-tonics seem to arrest or materially modify spermatorrhœa caused by chronic inflammation of the prostate. Every prac-

titioner knows from repeated failures how unsatisfactory all the usual modes of treatment are in these cases. Many, indeed, can hardly realize that the trouble is as serious as the patient's sufferings would indicate, and are inclined to attribute much of it to undue anxiety and worry on his part.

TREATMENT OF DISEASES OF THE PROSTATE BY LOCAL APPLICATIONS.

In the treatment of diseases of the prostate gland, I have obtained the most satisfactory results by the local application of medicaments directly to the prostatic portion of the urethra. I am inclined to believe that the astonishing and almost incredible results claimed by M. Lallemande for the *porte caustique* in spermatorrhœa and in impotence were due more to the direct antiphlogistic action exerted upon the prostate than to any special effects of the cautery upon the spermatic ducts. Practical experience has demonstrated that the use of escharotics for this purpose should be discouraged on account of their liability to leave hardened cicatrices, which interfere with the normal functions of the organs. If something of this character is indicated in the case, it is much less objectionable to employ the hydrarg. pernit. in the form of an ointment. Of the great number of cases, however, that have been under my care, very few required caustic applications. In the greater number I have found alterative and sedative applications, such as hydrarg. bichlor., iodoform, belladonna, ergotin, and cocaine muriat., meet every indication. It would be impossible, however, to lay down any strict inflexible formula for any therapeutic agent or combination that could be used indiscriminately. Nearly every case of prostatic disease, whatever its character may be, is "a law unto itself," and the particular therapeutic agent or combination suited to it must be governed by the pathological condition of the gland as developed by digital examination. But whatever remedy is indicated, it should always be applied in the form of an ointment, as comminution renders absorption easier.

In my own practice I have for a great many years applied ointments in this way with the most gratifying results. I employ the *porte caustique* of Lallemande, charging the cup of the projecting part with the particular ointment decided on for the case, instead of the silver nitrate. Passing the canula down the passage to the prostatic portion of the urethra, I project the cup containing the ointment, and allow it to remain usually about five min-

utes, turning it around occasionally during that time. I then withdraw the instrument, and the patient goes about his business, as the operation causes no suffering, and only a slight smarting, which passes off in a few minutes. I repeat these operations about once a week, sometimes twice, and it is seldom necessary to continue them longer than from six to twelve weeks. The effect is not only gratifying, but immediate. Patient and physician are not discouraged by waiting too long for tangible results. I have often had patients apply for treatment who had been under the care of physicians of unquestionable skill for months without appreciable benefit. In some of these cases nocturnal emissions occurred five or six times a week, and even oftener; in others almost complete impotency existed, the intromittent organ seeming as if paralyzed; in nearly all there was more or less trouble of one kind or another with the urine. Yet frequently a single application to the prostate has made a marked change, reducing the frequency of the emissions from four to six a week to once, increasing the tone of the parts, increasing erectile vigor, or materially lessening the urinary trouble, as the case might be.

There is one point in this connection to which I wish to call especial attention. The subcutaneous injection of ergot at the root of the penis for restoring erectile power, as recommended by Bartholow, is seldom practicable, and nearly always renders the part sore. The application of this remedy to the prostate, as I have described, is not only more effectual in cases of impotency on account of absence of erection, but attended by none of the objections to its use as a subcutaneous injection. I have frequently verified the correctness of this statement by incorporating it with whatever ointment I might be applying to the prostate in middle-aged and old men. Impotency, according to my experience, in middle life is oftener due to disease of the prostate than to failure of the generative functions.

A case in point was that of a gentleman of sixty, wounded on one of the gunboats in the attack on Fort Donelson, which battle gave me my first experience in practical surgery. This gentleman had received a gunshot wound in the loins, and as I found his bladder enormously distended from retention, I at first supposed that the spinal nerve-centre had been injured by the shot. But in attempting to pass the catheter I was obliged to insert a finger in the rectum to guide it, and noticed

that the prostate gland was very much enlarged. On questioning him, I discovered that he had been subject to attacks of retention of urine from congestion of the prostate for two or three years, and for a still longer period had lost the power of erection almost entirely, although the seminal secretion appeared to be abundant. It chanced that the only lubricant on hand for the catheter was a small wooden box of ointment, a compound of hydrarg. bichlor. cum belladon. et ext. ergotæ, which I had been using as a dressing for scrofulous ulcers on the legs of a patient at St. Mary's Hospital at Cincinnati, and which I had carried down to Fort Donelson in my coat-pocket. I used it on the catheter in the old gentleman's case simply because it was the only thing I had to oil it with, and without stopping to think much about it. Circumstances were such that he remained under my observation while recovering from the wound in the back, and, at his solicitation, I used the preparation several times afterwards on the catheter with which I drew his water, as it seemed to relieve the feeling of fulness in the rectum of which he complained, and enabled him to pass water with greater ease. A year later this gentleman visited me at Louisville, where I was then located, for the purpose of being catheterized, not so much on account of the difficulty in passing water, which, he stated, was measurably relieved, but to secure the use of a similar ointment to that formerly used. He informed me that not only was the prostatic trouble much better, but that nearly normal erections had returned. I continued the applications, using the *porte caustique* instead of the catheter, for some three or four months with such marked benefit that my patient, who was a widower, got married some six months later.

I merely mention this incident to show how we sometimes stumble upon important discoveries through the merest accident. Although there was nothing particularly novel in this method of treatment, it was new to me at that time, and even now the treatment of disease of the prostate by means of medicaments applied directly to the prostatic portion of the urethra has not received that patient investigation which its merits deserve. Some physicians do not seem to recognize the source of prostatic trouble. I have met with many cases in which the senseless operation of splitting up the meatus had been performed for urinary derangement due to an enlarged prostate.

In conclusion, I will add that my practice

for the past twenty years has been such as to bring me in contact with numerous cases of prostatic disease. In most of these cases the patients did not suspect that they were laboring under any prostatic affection, but applied for treatment either on account of spermatorrhœa, loss of sexual power, or urinary trouble. I have in many cases found it difficult to convince them that the source of trouble was in the prostate gland. Some, indeed, could not be convinced, having formed a theory of their own, derived from pernicious quack publications, and they of course were lost. But whenever the patient has had the strength of will, and, above all, the confidence in advice, to adhere faithfully to the treatment which I have here indicated, the relief has been as gratifying as it was marked and unexpected.

It is not by any means to be understood that these local applications are the only treatment required in such cases. They all require general treatment according to the indications pre-ent in each case, but the object of this paper is to emphasize the value and importance of local applications to the prostate, and it would extend it much beyond the original limits imposed upon it to enter into a discussion of the general management and medical treatment of these diseases, which I have considered at some length in a former monograph.

There is the same necessity for alterative treatment, renal resolvents, general and special nerve-tonics, and restorative medication, according to the individual peculiarities of each case, and the age and general physical condition of the patient. Local applications are not intended to supplant any of the usual means employed for anchoring frail humanity to earth awhile longer, but they supplement, aid, and assist them, and materially increase their efficacy and success, and render the results of our treatment more satisfactory and relief more certain and speedy.

Finally, medical practitioners should impress the fact upon their patients that the first serious indication of prostatic disease is some imperfection in the act of micturition, and *whenever any trouble is experienced in passing water for any considerable length of time, suspect disease of the prostate gland.*

189 WISCONSIN STREET.

THE ANTIPYRETIC ACTION OF ANTIFEBRIN.

BY DR. E. W. EVANS, EASTON, PENNA.
(From the private laboratory of Dr. Ott.)

PART II.—ON THE FEVERED ANIMAL.

SINCE the publication of Part I. in the April number of this journal, I have made the following experiments in order to observe the action of antifebrin in the presence of a pyrogenic agent, deutero-albumose being employed, it having been demonstrated by Ott and Collmar* that the albumoses and peptones were active heat-producing agents, the fever setting in at the end of the first half-hour and continuing for about three hours. The dose used by them being from .015 to .020 gramme.

In all of my experiments I have not used less than this, and in some cases more, getting a rise in all of from $.5^{\circ}$ to 1.4° in the first hour after injection into the jugular. And at the end of the hour, when the fever was still on the incline, the antifebrin was given in the same manner, and the animal replaced in the chamber of the calorimeter.

These experiments are certainly significant in the uniformity of their results, as will be shown, there being not a single case in which there was not a reduction both in the production and the dissipation of heat, although the doses of the pyrogenic and the antipyretic agents varied greatly.

Experiment 1.—Rabbit; weight, 1.88 pounds.

Upon reviewing the results of these experiments, as collected in the table, the

PLATE II.

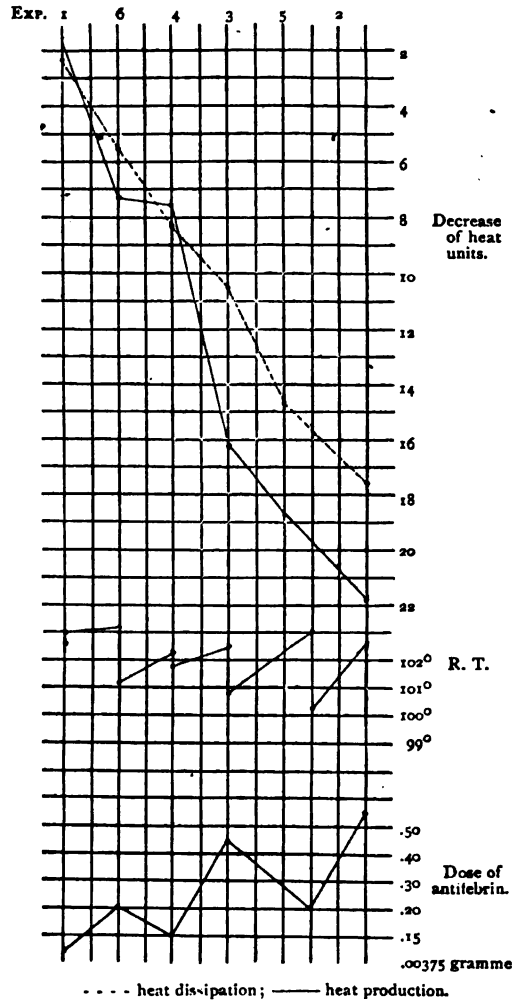

PLATE II.—The dotted line shows heat dissipation and the straight line heat production; the curves below the zero line, which is the normal line, represent so many units of decrease in heat production and heat dissipation after the use of the antifebrin.

The dose and temperature curves are below. Thus, in Experiment 3, the dose is .45 gramme, heat production and heat dissipation are diminished, and the temperature fell from 102.5° to 100.8°.

Table No. 3.—Antifebrin Experiments on Fevered Animals.

Experiment.	Duration.	Weight of animal.	Dose of antifebrin.	Hourly heat dissipation.				Hourly heat production.

uniformity previously spoken of becomes quite evident. But perhaps the accompanying plate, where I have arranged the curves of heat production and heat dissipation in direct relation to the temperature and the dose exhibited, may show it still more clearly.

In the calorimeter experiments made with albumoses by Ott and Collmar it was determined that the fever obtained was produced by an increase of heat production and a decrease in heat dissipation. In my experiments the temperature reduction, which occurred in

two-thirds of them, was due to the great decrease of heat production in excess of the accompanying decrease in heat dissipation; since in the two experiments where the temperature continued to rise after the antifebrin had been injected, the reduction of heat production was small in comparison with the reduction in heat dissipation.

In most of these experiments, particularly when large doses had been given, a peculiar cyanotic condition of the ears appeared shortly after the administration of the antifebrin.

Upon analysis of the blood in these cases with the Sorby-Browning micro-spectroscope, the third band of methæmoglobin was distinctly seen. The drug evidently alters the coloring-matter of the blood, progressively changing and reducing the oxyhæmoglobin to methæmoglobin.

This cyanosis has also been frequently noticed by many observers in the clinical application of the drug.

In conclusion, it is evident that acetanilide is a powerful, safe, and certain antithermic agent, and that its antipyretic effect in fever is due to the reduction it causes in the amount of heat produced; whether by direct stimulation of the inhibitory heat centre, paresis of the spinal heat centres, or by an action on the tissues themselves, remains to be demonstrated.

THE INFLUENCE OF ANTIFEBRIN, SALICYLIC ACID, AND CARBOLIC ACID ON NORMAL AND ABNORMAL BODILY TEMPERATURE.

By H. A. HARE, M.D. (UNIV. OF PA.).*

SOME months since there appeared in the GAZETTE quite a lengthy study on fever, and the agents which produced and combated it, by Dr. Wood, Dr. Reichert, and myself, and the following series of experiments may in a manner be considered as a continuation of the former ones.†

* Demonstrator of Experimental Therapeutics and Instructor in Physical Diagnosis in the University of Pennsylvania.

† For the manner in which fever was produced, and any other details concerning the methods of this research, the writer must refer to the paper just mentioned.

The writer desires to call attention to the statement made in this joint paper that a thermogenic substance in the pepsin was a pepsin-peptone, as his researches make this somewhat doubtful. He has found that certain commercial pepsins charged with peptone fail absolutely to produce increase in bodily temperature, but, on the contrary, decrease it. This is of course in accord with

At the time these experiments were begun no calorimetrical investigations as to the manner in which these agents act had been performed, and it is only within the last few weeks that a short but elaborate paper has appeared in this journal on the influence of antifebrin on bodily heat by Dr. Evans, of Easton, Pa. With the exception of this last-named investigation the profession possesses the results of no true calorimetrical observations on these three constantly used drugs, and it was this dearth of information which provoked these experiments.

The objects of the research have been, therefore, as follows:

First.—To determine the effect of each drug on normal temperature in the animal, which was free to come and go as it chose.

Second.—To discover what changes came about in the circulation during the alterations in the normal bodily temperature.

Third.—To determine what changes in the circulation occurred when the drug was influencing bodily temperature above normal.

Fourth.—To study in what manner these changes in temperature were produced, both with and without fever, or, in other words, whether these agents reduced bodily heat by altering heat production or dissipation, or both.

I. ANTIFEBRIN.

I have made ten experiments on the influence of antifebrin on normal rectal temperature, which show that this drug possesses to a marked degree the power of reducing bodily heat when no fever is present. In every instance there followed after the injection of the drug a very considerable fall, in some cases amounting to more than a degree Fahrenheit.

The following experiments, which agree in all respects with the others made on this point, will serve as examples:

Experiment 1.—Rabbit; weight, 2½ pounds.

Time.	Drug.	Rec. temp.
A M.		
11.05	102½°
11.07	½ gr.

the well-known fact that the commercial peptone of Grûbler decreases animal temperature. It is plain that if the fever-producing agent really is a peptone, there must be two peptones in the commercial article, one of which decreases and the other increases bodily temperature. The relations of peptones to albumoses is so exceedingly close that it is quite probable that the so-called pepsin-peptone may be an albumose.

On studying the influence of antifebrin on bodily temperature and its relations to arterial pressure, we find that under normal conditions it generally produces a fall of temperature and a fall of pressure; but this is not by any means a constant action of the drug, since in Experiment 6 we see that though the temperature was decreased there was not a fall, but a rise of arterial pressure. This one exception would have but little weight against the others were it not that the fall of arterial pressure, when it did occur in the others, was not steady, but interrupted by temporary and unexplained rises; in other words, pressure and temperature did not fall side by side. Notwithstanding this fact, however, it is a just and proper conclusion that antifebrin in

producing a lowering of temperature also acts as an arterial sedative.

Just here it may be well to call attention to the action which the drug possessed in Experiment 7, namely, causing sudden cardiac failure from an unknown cause. In this experiment the animal died suddenly, so suddenly that the arterial pressure fell to zero from a considerable height in ten or fifteen seconds.

Death came without a tremor, a gasp, or any sign of an approaching cardiac failure.

On making an autopsy a small clot was found in the left ventricle, and there was also a long, well-formed clot extending from the canula in the carotid to the innominate artery.

The death was evidently due to this cause.

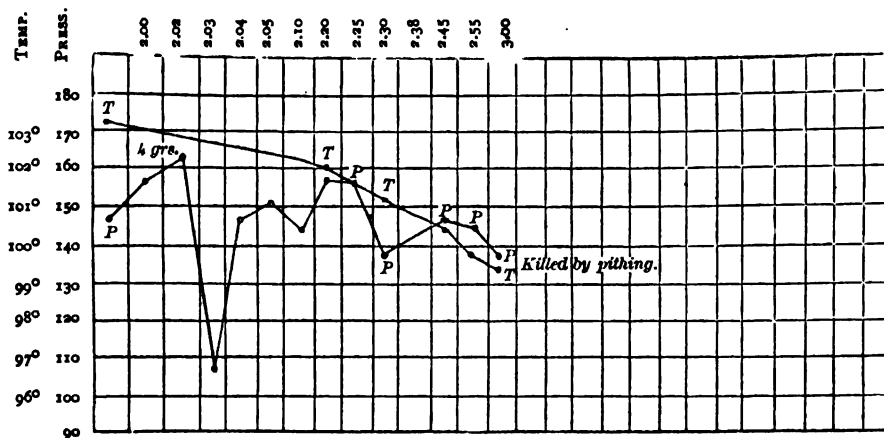

When antifebrin is injected into the jugular vein in an animal suffering from the pepsin fever it apparently has little, if any, effect on the pyretic condition, and both temperature and pressure mount upwards as if free from any inhibiting influence. This is the more remarkable since we have already discovered that this drug depresses normal temperature, but it may be that it is not able to cope with systemic changes produced by the pepsin. A glance at the charts will show this statement to be a fact, and we will now pass on to a consideration of its action on the production and dissipation of heat, hoping thereby to discover some cause for this rather remarkable result, for, as is well known, most drugs which depress normal temperature possess still greater powers over abnormal temperature.

From the experiments on heat production and dissipation in the normal animal we are able to draw the following conclusions, viz., that this drug reduces bodily temperature both by increasing dissipation and decreasing production. (See Experiments 12, 13, 14, and 15.)

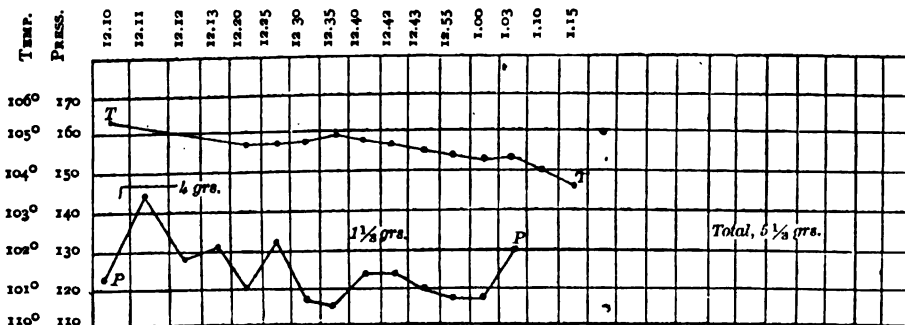

By the above the writer does not mean to insinuate that antifebrin decreases temperature by a double action necessarily in any one case, but rather that in one case the temperature is decreased by increased dissipation, and in another by decreased production.

CONCLUSIONS.

1. *Antifebrin* effects marked depression of normal bodily temperature.

2. During the depressing action of antifebrin on normal temperature it seems to cause a slight fall in arterial pressure, although this is by no means a constant result, as it may cause a rise.

In the opinion of the writer, however, this drug in lowering temperature acts as an arterial sedative.

3. Notwithstanding the fact that antifebrin influences to such a marked degree normal bodily heat, it seems to possess little power

against the pyrexia produced by the introduction of pepsin into the blood, since under these circumstances the hitherto depressed pressure rises, as does also the bodily heat.

This curious fact must depend on some organic changes produced by the digestive ferment.

4. This drug reduces *normal* temperature apparently by influencing both production and dissipation.

5. Antifebrin in fever chiefly reduces the high temperature by decreasing heat production, and is therefore a valuable antipyretic.

(To be continued.)

A CLINICAL STUDY OF ANTIPYRIN AND ANTIFEBRIN.

By G. WALTER BARR, M.D., BRIDGEPORT, ILL.

I AM just convalescing from an attack of fever lasting five weeks, during which I made a careful study of antipyrin and antifebrin. The disease was neurasthenia complicated with malaria. My notes from observations taken every fifteen minutes for a long period of time would almost fill this journal, and therefore only generalizations are given.

The dose of antipyrin taken was at first 10 grains, which was increased gradually to 23 grains for a person of nervous temperament, who requires average doses of other drugs. Tolerant of antipyrin increases after a week's use of the drug, and the dose must be constantly increased if it be used long.

Ten minutes after the ingestion of a dose of antipyrin in gelatin capsules an aromatic warmth is felt in the stomach to a slight degree, and ten minutes later a glow seems to spread over the whole body, and is followed by sweating, and in a neurasthenic, irritable person, considerable tranquillity of mind ensued five minutes later. This psychological effect lasted half an hour.

In thirty-five minutes the temperature fell 1° F. The sweating gradually lessened, and ceased in two and a half hours after the drug was taken. In two hours from its ingestion the temperature had fallen about 3° F. This was regardless of the temperature when the antipyrin was taken, which varied from 101° to 105° F. However, it never lowered the temperature below the norm.

The above phenomena were constant. Almost constantly, about fifteen minutes after the dose was taken, the breath had an odor of

ol. carui, sometimes very strong and often more faint. This lasted for about an hour.

The fever invariably began to rise in two and a half hours after the dose of antipyrin was taken, and the antipyretic effect was certainly only transitory. The after-effect was a general, indescribable feeling of greater *malaise*. The only effect on the pulse was its slowing, but the pulse was affected in great disproportion to the temperature and became, on a basis of temperature, abnormally high, though absolutely lower. There was little or no change in the amount and gross appearance of the urine.

Antifebrin was used after antipyrin was begun, and at the same time alternately with the latter. The dose ranged from 5 grains to 13 grains. A tolerance was established to it. A number of times the same caraway odor on the breath was perceived, causing very interesting speculations as to the resultant of the corporeal chemistry upon both antipyrin and antifebrin. The aromatic, stomachic sensation was very seldom felt, the bodily glow and perspiration being generally the first effects noticed from antifebrin when the caraway breath was absent.

Antifebrin causes a fall of temperature in an hour or an hour and a half after its ingestion in gelatin capsules. The fall from one dose is about 4° F., though the norm was never passed in its downward tendency. The decline was maintained for an average of six hours, after which the temperature began to rise again. It has no permanent effect on the fever if its constant use for several weeks is a criterion. It gently stimulated the mind and affected the muscular system almost precisely like coca. I was several times as strong while under the influence of antifebrin as at other times, and intellectual indolence gave way to more energy. The tonicity of the pulse was increased and the rate slowed. Its effect on the pulse resembles that of convallaria majalis. Antifebrin is decidedly diuretic and less diaphoretic than antipyrin. There were no after-effects, not even the depression to be expected after the stimulation it produced. Once the dose of antifebrin had not the slightest physiological effect. The conditions were exactly the same as at other times as near as I could discover, after very careful examination. An ordinary dose of antipyrin immediately acted as usual, and antifebrin afterwards did well. Perhaps some internal conditions hardened the capsule. Every dose of both drugs was taken

in an empty stomach. My curiosity led me to wish for another failure that I might try another dose of antifebrin, but the opportunity never came. To sum up,—

ANTIPYRIN.	ANTIFEBRIN.
Lowers temperature in half an hour.	In an hour or more.
Effect lasts two hours.	Effect lasts six hours.
More diaphoretic.	More diuretic.
Depressing after-effects.	No after-effects.
Cerebral sedative.	Cerebral vaso-motor and muscular (?) stimulant.
Dose, 15 to 30 grains.	Dose, 5 to 15 grains.
Tolerance from continued use.	Ditto.

The above table will suggest the selective use of the two drugs. From the patient's point of view (which is really coincident with the physician's) antifebrin is much to be preferred in continued fevers, because the dose is one small capsule instead of three; the effect lasting so long requires one-third the number of doses; the tonic stimulation excels the depression and after *malaise*, and the cost is one-fourth that of antipyrin. The antipyretic action of antifebrin is as strong or stronger than that of antipyrin, and its only objection is its slowness of action. In insolation and other cases where a quickly-acting antipyretic is necessary, and when it has a specific action on the pathology of a disease, as is claimed in rheumatism, antipyrin is to be preferred. Whenever one can wait an hour for the antipyretic action to begin, I greatly prefer antifebrin, and I know the patient will also. I believe its stimulant or tonic effect to be very valuable in weak patients.

THE THERAPEUTIC EQUIVALENTS OF SALTS OF QUININE.

According to BOYMOND, in *Archives de Pharmacie*, the equivalents for 1 gramme anhydrous quinine are, of the hydrate, 1.16 gramme; acetate, 1.18 gramme; basic muriate, 1.22 gramme; lactate, 1.27 gramme; basic hydrobromate, 1.30 gramme; valerianate, 1.31 gramme; basic sulphate, 1.34 gramme; neutral sulphovinate, 1.39 gramme; arseniate, 1.44 gramme; basic salicylate, 1.45 gramme; citrate, 1.49 gramme; neutral hydrobromate, 1.64 gramme; neutral sulphate (bisulphate), 1.69 gramme; hydroferrocyanate, 1.77 gramme; acid hydriodide, 1.78 gramme; tannate, 4.42 grammes; citrate of iron and quinine, variable; brown quinine, variable.—*National Druggist*, May 13, 1887.

EUCALYPTUS HONEY.

IN *Le Progrès Médical* for April 16, Dr. Thomas Caraman describes the discovery and the medical and chemical properties of a peculiar bee production, to which is given the name of black honey. In May of 1884, M. E. Guilmeth, the French naturalist and traveller, found in a wilderness in the central part of Australasia a number of enormous eucalyptus-trees, and at a great height from the ground perceived a number of dome-shaped, brownish masses, which he at first supposed to be excrescences. Late in the afternoon his attention was called to the going in and out of swarms of black insects from an opening in the dome-shaped masses, and finally, after many hours of labor, one of the trees, whose diameter was said to be between nineteen and twenty metres, was cut down. Out of a single honey receptacle M. Guilmeth took as much as eleven thousand pounds avoirdupois. The insect which secretes this honey is said to be new to science, and has been given the name of *apis nigra mellifica*. It is very small and black, and the languet of the workers is much more developed than that of the or-

dinary bee. All attempts to domesticate it in Tasmania have failed, but it is said that some success has been achieved in Algeria in the neighborhood of plantations of eucalyptus.

A remarkable fact stated by Dr. Caraman is that the ordinary bee condemned to feed upon the flowers of the eucalyptus-tree rapidly dies off.

The so-called black honey is at ordinary temperatures a somewhat transparent, syrupy, thick, homogeneous, dark orange-colored liquid, with a peculiar odor similar to that of eucalyptus, is very soluble in water, milk, and wines, and much less in alcohol. Its fermentation is exceedingly difficult, on account of the large quantity of levulose which it contains. Its specific gravity is 1.44, and it radiates the polarized ray at 22 degrees.

1000 parts of it contain in round numbers 611.6 parts of sugar, mostly levulose, 1.8 parts of ash, 215.6 parts of water, and 171 parts of various substances, comprising eucalyptol, eucalyptene, terpene, cymol, and odorous and resinous matters.

When black honey is given freely to dogs, dissolved in warm milk, it produces a very surprising reduction in the number of cardiac pulsations. Thus, in a feverish dog, the pulse fell from one hundred and twenty-five to seventy a minute; this fall was accompanied by a lowering of the temperature one degree centigrade; the effect lasted twenty-four hours, with a slight tendency to sleep, but with no symptoms of toxic depression.

When a tablespoonful of the honey was given to a man, dissolved in a little warm water or milk, after some minutes a slight agreeable sensation of warmth filled the whole body. In about half an hour eliminations of the active principles through the pulmonic mucous membrane commenced. The voice becomes more clear and sharper, and the breath perfumed. It seems as though the lungs themselves were more elastic.

When Dr. Caraman, who affirms that he is somewhat fleshy, took four tablespoonfuls a day for a week there was marked lessening of shortness of breath on ascending steps, and slight increased diuresis, with an augmentation of the urea. The urine acquired an odor resembling that of the *Cassie farnesiaum*, an Algerian plant, from which is prepared the perfume habitually sold under the name of new-mown hay.

Dr. Caraman believes that this honey will be a valuable remedy in the treatment of bronchial catarrhs, and that it acts as a sedative to the heart-beat, in a manner similar to

digitalis. He thinks also that it will be of practical value as a febrifuge and as a bactericide. He hopes much from it in the destruction of the bacilli of phthisis and the pneumococcus of pulmonic inflammations, and even asserts it has been employed in typhoid fever with success, and that in leucorrhœa, whether from accident or constitutionally, it causes the affection rapidly to disappear, and kills the leptosis vaginalis and the oxyures. He has also found it of great use in the treatment of gonorrhœa and diseases of the kidneys, bladder, and urethra, and affirms that it acts more energetically than the pobatha or sandal oil.

It is not at all probable that this substance will fulfil all the expectations of its enthusiastic advocate, but if it only do a portion of what is claimed for it, it will be a valuable addition to our therapeutic resources. If it be produced in as enormous quantities as are described by M. Guilmet, it ought eventually to find its way into general commerce and be obtainable at a merchantable price. We do not know, however, of any of it as yet reaching this country. If it grow in importance it is probable that artificial eucalyptus and honey will be offered for sale, and it is, therefore, a matter of importance that not only the physical and medicinal properties of this drug be very carefully described, but that some test of purity be worked out.

TREATMENT OF CHRONIC SYPHILIS.

IN the treatment of chronic syphilis but too often it happens that the patient improves up to a certain point and then ceases to respond to the administration of anti-syphilitic remedies, even when they be combined with the most careful hygienic treatment and the exhibition of tonics, etc.

Any remedy which offers a fair probability of being able to carry on the amelioration of the disease under these circumstances is one worthy of very careful consideration by the profession.

Many years ago Mr. Carmichael, of Dublin, asserted that he found the oil of turpentine often of unquestionable value in the treatment of obstinate and long-continued syphilitic iritis, and during the service of Mr. G. J. Guthrie, of the Royal Ophthalmic Westminster Hospital, the practice was accompanied with alleged excellent results.

Mr. Jabez Hogg of the same hospital has recently (*Medical Press and Circular*, April

27) published the account of a case in which, after the failure of mercurials by the mouth, by inunction, and fumigation, conjoined or alternated with the use of mydriatics, tonics, iodide of ammonium, iron, etc., turpentine succeeded. It was given in $\frac{1}{2}$ -drachm doses, suspended in mucilage, three times a day after meals. For the first week an inunction of a twenty per cent. solution of the oleate of mercury was freely employed, but this was then laid aside, and for four months the turpentine alone was steadily persevered in. Not only was the patient's general health improved, but the corneal opacity of the iritis gradually disappeared, and at the time of the making of the report the serous exudations and other local changes in the eye had so far been absorbed or ameliorated that the vision was almost what it was before the first inflammatory attack, fourteen months previous.

THE DIURETIC ACTION OF MERCURIAL PREPARATIONS.

THE diuretic action of calomel, known to the older physicians, has been, as the readers of the *GAZETTE* are familiar, again brought to the attention of practitioners, and we have published testimony from a number of different observers which indicates that under certain circumstances calomel is one of the most active diuretics that we possess.

That this diuretic action is not peculiar to calomel, as has been claimed by a number of writers, but is also, though perhaps to a less degree, possessed by other mercurial preparations, has been brought into prominence by Dr. Rosenheim in a paper read before a recent meeting of the Verein für Innere Medicin of Berlin (*Therapeutische Monatshefte*, April, 1887).

The author employed corrosive sublimate, yellow iodide of mercury, and the amidato bichloride in amounts of from $1\frac{1}{2}$ to 2 grains given daily. These preparations of mercury also proved themselves active diuretics in these large doses, but they produced more irritation in the intestinal canal than calomel, and also fell behind calomel in the degree of diuresis. On the other hand, the stomatitis produced by these mercurial preparations was but slight. Diuresis only follows when large doses of some mercurial preparation are rapidly absorbed, seemingly indicating that the production of diuresis is due to the acute mercurialization of the organism. The correctness of this view is ren-

dered more probable by the large amounts of mercury which are excreted through the urine.

Dr. Rosenheim's experiments with calomel still further strengthen its position as a diuretic. He employed it in sixteen cases of heart-disease complicated by dropsies, in several of which kidney complications were also present. In nine of these cases a prompt diuresis and disappearance of the œdema followed the use of calomel. In four its action was but moderately successful, and in three it entirely failed. It is worthy of notice that in all these cases before calomel was administered digitalis had been tried and proved inefficacious. Since it has been found that calomel has no direct action either on the heart or kidneys, kidney-disease offers no contra-indication to the use of calomel for the purpose of producing diuresis. In fact, Dr. Rosenheim has employed calomel for this purpose in purely nephritic dropsy. It is true that the results, however, were unfavorable. In the greater number of patients to whom calomel was administered a more or less severe stomatitis was produced, and in nearly all cases diarrhœa.

In the discussion which followed the reading of Dr. Rosenheim's paper, Dr. Leyden reported that he had treated three cases of cirrhosis of the liver with calomel. In one failure had resulted, in one marked but temporary relief, and in one a permanent amelioration.

In the treatment of dropsy from heart-disease, he regarded calomel as a valuable contribution to our therapeutic measures.

Fürbinger, on the other hand, claimed that the diuresis produced by calomel, although perhaps occurring in a high degree, was invariably ephemeral, and he regarded its mode of production as dependent upon a direct action on the glandular epithelium of the kidney, since calomel never acted as a diuretic in œdema dependent upon previous parenchymatous nephritis.

Dr. E. Biró, of Budapesth, has also confirmed the general experience of others as to the marked diuresis which follows the use of calomel, and although in his practice stomatitis, colic, and diarrhœa were frequently produced, he regards these complications of but little moment in view of the powerful action of the remedy. He has found that the degree of diuresis depends upon the intensity of the œdema, and he relates one case of mitral insufficiency in which the amount of urine was increased on the fifth day from eight hundred to six thousand eight hundred cubic centi-

metres. For the stomatitis, which is at the worst merely transient, he recommends a mouth-wash of potassium chlorate, and small doses of opium powder for the diarrhœa and colic.

Terray (*Pest. med. chir. Press.*, 1886) and Weinstein (*Wien. med. Blätt.*, 1887, No. 7, p. 206), whilst affirming the diuretic effects of calomel, as reported in the *Medical Chronicle*, May, 1887, draw attention to the evils which may follow its administration. Terray states stomatitis occurred in all his cases, and its intensity seemed directly proportional to the diuresis.

Weinstein records a marked increase in the excretion of urine in four cases of pleural effusion, two cases of cirrhosis of the liver, and one case of Bright's disease. But he found great evils arise from the administration of calomel as a diuretic, profuse diarrhœa, stomatitis, and salivation sometimes occurring after even small doses. The diuretic influence of the drug, he says, is not of long duration, and he recommends it chiefly in ailments which have run their acute course, leaving œdema behind them, and in those where the mercurial itself is likely to exercise a beneficial effect, e.g., in pleural exudations.

PREVENTION OF DIPHTHERIA.

A RECENT document issued by the State Board of Health of Michigan is, in its few brief paragraphs, the most eloquent plea we have ever seen for the establishment and maintenance of Boards of Health, and shows that when this department of the Public Service is properly organized with suitable *personnel*, and clothed with sufficient power, it is capable of saving numerous lives.

During the year 1886 there occurred in the State of Michigan 461 outbreaks of diphtheria. Of 243 of these outbreaks there is no clear record as to an attempt to restrain the spread of the disease by isolation or disinfection. Of the remaining 228 outbreaks the statements are clear. In 102 outbreaks no attempt was made either to isolate the earlier patients or to disinfect the apartments or surroundings; the result was that there were 1650 cases of the disease, with 329 deaths, or an average of 16.18 cases and 3.23 deaths to each outbreak. In 116 outbreaks isolation and disinfection were both more or less rigidly enforced; the result was that there were only 332 cases and 77 deaths, or an

average of 2.86 cases and .066 deaths to each outbreak. According to these figures nearly 1500 cases of diphtheria and 300 deaths were prevented by the local Boards of Health.

THE INDEX MEDICUS.

WHEN Mr. George S. Davis, after the failure of the firm of George P. Leypoldt to put the *Index Medicus* upon a sustaining basis, undertook the publication of this work, we spoke earnest words of commendation, and urgently solicited support for the enterprise from our readers. It is, therefore, with great pleasure that we note the passage of the following resolutions at the recent meeting of the Tennessee State Medical Society in Nashville :

"WHEREAS, The medical profession of this country has for years taken a great interest in the permanent establishment of the *Index Medicus*, first published by Leypoldt, of New York City, in 18—; and

"WHEREAS, By the death of this public-spirited friend of science and literature the current cyclopædia book of reference was *in articulo mortis*; and

"WHEREAS, Mr. Geo. S. Davis, secretary of the firm of Parke, Davis & Co., Detroit, Mich., at the earnest solicitation of medical editors and writers in all parts of the world, undertook to keep it alive; therefore, be it

"Resolved, That the Medical Society of the State of Tennessee do hereby express its high appreciation of this liberal aid given investigators everywhere, and earnestly hope the profession will not allow the final effort to maintain a great periodical which has reflected special credit on American medical science to fail because of indifferent and niggard support."

Reports on Therapeutic Progress.

THE TREATMENT OF LUPUS.

At a recent meeting of the Nottingham Medico-Chirurgical Society, Mr. CHICKEN (*Lancet*, April 23, 1887) read a paper on the "Treatment of Lupus and its Allied Disorders." He took epithelioma as a type of the diseases allied to lupus as exhibiting a cutaneous or mucous cell development, infiltrating or penetrating subjacent tissues, and depending on a specific morbid impulse. In the case of an affection of the skin, or those

parts which could be safely operated upon, he advocated the treatment of the part by thoroughly scraping away, as far as possible, the new growths, and then the free rubbing in of iodoform. In those instances where the situation was such that this could not be done,—as, for example, in epithelioma of the cervix uteri,—he employed the frequent application of iodoform. Although, in these difficult cases, it was not possible to eradicate the disease, it modified the subsequent progress and unpleasantness of the malady in a marked degree. In epithelial stricture of the rectum, he first washed out the bowel with warm water, and then injected into the stricture from two to four drachms of iodoform daily by means of a special insufflator. In exposed situations, where the treatment could be thoroughly carried out, the result was very satisfactory. He showed two cases, one of lupus and one of epithelioma, both of which had been operated upon in the manner described, some years ago. There had been no recurrence. Mr. Chicken drew the following conclusions: 1. That lupus and epitheliomata are types of a cellular infiltrating new growth, and are best treated by scraping with a blunt knife, and when the surface has been as far as possible cleared from the invading cells, by rubbing in a remedy, of which iodoform is a good example, with the object of penetrating to those outlying detachments which the knife has not reached. 2. That when the growth is situated in a part that can be readily attacked the treatment gives ground for a good hope of recovery, at any rate better than excision. 3. That when the situation is such that scraping cannot easily be done, the copious insufflation of large quantities of iodoform is practically without risk and of great benefit to the condition of the patient. 4. Iodoform is specially applicable, because it seems to exert a specially sterilizing influence on the growth, and is capable (by virtue of its volatile and peculiar penetrating properties) of permeating tissue more than an insoluble non-volatile substance. It is quite harmless and unirritating to healthy structures.

ELECTRICITY DURING AND AFTER LABOR.

There are probably very few complaints and infirmities for which electricity in one form or another has not been tried, with varying success, it is true, but this uncertainty in its effects is attributable not only to the greater or less appropriateness of its employment,

but also to the greater or less manipulative dexterity of the person using it. A case is reported in a French medical journal in which its application both for the purpose of stimulating labor, and subsequently for cutting short an attack of violent post-partum hemorrhage, was attended with great success. When the flooding began, the removal of the clots with internal manipulation of the uterus, together with injections of vinegar and hot water, were tried, but failed to excite uterine contraction. The medical attendant then took advantage of the proximity of a strong battery to cut short the attack. He placed one pole in the hand of the patient, and took hold of the other himself. With his disengaged hand he grasped the uterus through the abdominal walls. The experiment was a disagreeable one for the doctor, but he had the satisfaction of seeing the uterus contract promptly and firmly, and the hemorrhage ceased. It is, of course, impossible to affirm that the result in this case was due directly, and only, to the stimulus of the current, but there is every reason to believe that the effect of a strong and interrupted current on the muscular fibres of the uterus would be likely to favor such a result. The experiment is certainly one worth repeating, and we would commend it to the attention more particularly of lying-in institutions, where it would not be difficult to arrange for a suitable apparatus being kept ready for immediate use. In private practice, too, in cases where flooding for some reason or another is feared, it would be well for the practitioner to provide himself with the necessary paraphernalia, since no agent which offers any resource against such a terrible enemy as post-partum hemorrhage is to be neglected in these cases.—*Medical Press*, April 13, 1887.

ANTIPIRYN AS AN ANODYNE.

According to the Paris correspondent of the *London Lancet*, April 30, 1887, at a recent meeting of the Academy of Sciences, PROFESSOR GERMAIN SÉE made a communication upon "The Treatment of Pain by Antipyrin." This substance, which was discovered by Knorr in 1884, was first employed, as its name implies, for lowering the temperature, and it was expected that it would prove useful in typhoid fever, articular rheumatism, and other acute affections. It has not, however, been

as satisfactory in its action as was anticipated, and if the temperature can be by its use lowered at will, it does not seem to exercise much effect upon the process of disease. But according to M. Germain Sée, antipyrin is the remedy, *par excellence*, for pain, and far superior in every way to antifebrin. In fifteen cases of subacute rheumatism, or hydrarthrosis, treated unsuccessfully by salicylate of soda and ignipuncture, the pain and swelling disappeared in a few days, and, the medicine being continued, there was no relapse. The same effect was observed in cases of acute gout, both primary and secondary to chronic gout with chalky deposits. Antipyrin, to the extent of from 60 grains to 90 grains a day, removed both pain and swelling in from two to four days without any bad effect either on the heart or kidneys. But it is, above all, in nervous pain that its action is most remarkable. A first group comprises four cases of facial neuralgia, one of which was inveterate, six of migraine, with one failure, and four headaches. In a second series are classed five cases of sciatica, one of simple neuritis, two of diabetic neuritis, and two of neuritis with zona (one failure). Cases of lumbago and muscular rheumatism make up a total of eighteen. The third category relates to five cases of locomotor ataxia, in four of which the pains were removed by antipyrin. In the fifth instance it failed, as did also antifebrin. The last group comprehends those affections of the heart, aorta, and coronary arteries in which angina is a most painful symptom. In six patients with cardio-aortic disease, and in three others with aneurism, the painful manifestations disappeared entirely, without any evil effect being caused by the medicine on the strength or regularity of the cardiac pulsations. The dose given by M. Sée is from 3 to 6 grammes daily. If too much is given at one time, nausea and giddiness may supervene, but when the whole amount is divided into small repeated doses of half a gramme, no disagreeable effects are observed. Antipyrin may be given and continued for a length of time with but little risk. Antifebrin, on the other hand, is dangerous when administered in doses exceeding 1 gramme. It causes hæmoglobin to pass into the condition known as metahæmoglobin, and the blood, losing part of its oxygen, becomes of a chocolate color, cyanosis and collapse being the consequences. From laboratory experiments it is found that reflex excitability to electricity is diminished by antipyrin, and the sensory perceptivity of the cord is lessened.

NARCEINE.

Some experiments made by M. LABORDE with narceine specially prepared by M. Duquesnel, so as to be free from morphine and codeine, appear to have given results varying considerably from those obtained on previous occasions with what may be presumed to have been less pure preparations. M. Laborde states (*Archives de Pharm.*, April 5, p. 183) that he found this narceine much more active than any he had used before. A dose of 2 centigrammes caused the disappearance of insomnia in an adult, and in case of acute or chronic catarrhal bronchitis it rapidly relieved the cough. The quantity administered can be carried to 4 centigrammes, but it should be given in fractions of a centigramme at a time. It also soothes the paroxysms of whooping-cough in children, and M. Laborde recommends its administration for this purpose in a teaspoonful dose containing $\frac{1}{4}$ of a centigramme of narceine. Its effect when injected subcutaneously into dogs, in quantities of 1 to 3 centigrammes, is described as differing remarkably from that of morphine, the pure narceine producing a quiet, natural sleep, whilst with morphine there is considerable disturbance.—*Pharmaceutical Journal and Transactions*, April 30, 1887.

THE DIFFICULTIES IN ESTABLISHING
NATURAL RESPIRATION AFTER
TRACHEOTOMY, AND THEIR
TREATMENT BY TRACHEAL
CATHETERIZATION.

At a recent meeting of the Clinical Society of London, MR. BILTON POLLARD referred to three cases illustrating the difficulties in establishing natural respiration after tracheotomy, and drew attention to their treatment by tracheal catheterism (*Lancet*, April 30, 1887). The difficulty in getting rid of the tube after tracheotomy was by no means uncommon, and in two of the cases related it persisted after most determined and persevering attempts had been made for more than a year and a half by the usual methods. Two of the cases had been for a long time under the care of Mr. Godlee, and had passed into Mr. Pollard's hands when he succeeded Mr. Godlee at the Northeastern Hospital for Children. The first case was a boy aged two and a half years, on whom tracheotomy had been performed for laryngitis. For eight months frequent attempts were made to dispense with the tube. Mr. Godlee then catheterized the larynx without benefit. Five

and a half months later a piece of india-rubber tubing was passed through the larynx from the mouth to the tracheotomy wound, and left in position for forty-eight hours, without any improvement in laryngeal respiration. The operation was repeated four months later without success. A year and seven months after the tracheotomy Mr. Pollard passed a tracheal catheter from the mouth through the glottis and into the trachea, beyond the tracheotomy opening. It was retained for thirty-one hours, and after its removal the patient continued to breathe through his mouth. The tracheotomy wound was firmly healed in a fortnight, and the child had been perfectly well for the six months that had passed since the operation. In the second case (a boy aged 6) the windpipe had been opened for laryngitis. Three months after the operation, all attempts to get rid of the tube having failed, Mr. Pollard passed the tracheal catheter, and in doing so dislodged a piece of granulative tissue, which was coughed up. Pneumonia followed in this case, but the patient was nevertheless cured, and was discharged a fortnight after the operation. He remained perfectly well for the three months that had passed since the operation. In the third case (a boy aged 4) the operation had been performed for impaction of a foreign body in the right bronchus. For seven months attempts were made to get rid of the tube. Mr. Godlee then removed granulative tissue from the trachea and catheterized the larynx. The latter procedure was frequently repeated during the next three and a half months. Two years and three months after the tracheotomy Mr. Pollard found the vocal cords adherent; he separated them, and, after dilating the glottis with Lister's sounds, passed the tracheal catheter, which was kept in position for thirty-eight hours. It was not until three weeks after this operation that the patient breathed through his mouth alone. The boy's voice returned, but after four weeks laryngeal respiration was so difficult, owing to the vocal cords having grown together again, that the trachea had to be reopened. The only difference between the plan Mr. Pollard followed and that which Mr. Godlee adopted was that, by keeping the tube in the trachea whilst the tracheotomy wound was allowed to close, the patients were left, on its removal, without the opportunity of making use of the passage which, from constant employment, had become for them the natural one. In the first and second cases the chief cause of ob-

struction was laryngeal spasm, but in the second there was also a growth of granulative tissue. In the third case there was a genuine stricture of the larynx, and the tracheal catheter served as a means of continuous dilatation; the result in this case showed that the dilatation should have been employed for a longer period. In two of the cases the tracheotomy incision had divided the cricoid cartilage, and Mr. Pollard suggested that this method of operating might be a cause of the difficulty of re-establishing laryngeal respiration in those cases.

MR. HOWARD MARSH thought that in performing tracheotomy it should not be forgotten that the trachea was a canal, like the urethra, lined by delicate mucous membrane. Ulceration and granulation-tissues were frequently developed under the influence of the mechanical irritation of the tracheotomy tube. The fenestra in the tube was often the offending point, and when situated posteriorly then a hernial-like protrusion of the posterior wall might become the seat of granulations. He advocated the use of tracheotomy tubes with movable necks, and with a round, not bivalve, body. The surgeon should have an assortment of tubes to fit different cases, for in some the neck was very shallow, in others very deep, and so forth. He doubted whether all the cases could be successfully treated as Mr. Pollard's, and related a case in which no lumen through the larynx, which was full of granulation-tissue, could be detected on examination. Such a case was likely to prove hopeless under any method of treatment. The lapse of time was an important item in the cure of such cases, for cicatrization might occur meanwhile, and the natural growth and enlargement of the respiratory passages would come into operation. He mentioned a case of stricture of the trachea from permanent contraction which occurred in a child, now a woman, aged 25, but without any recovery of breathing power.

MR. C. H. GOLDING-BIRD considered that Mr. Marsh exaggerated a little the harm done by the fenestra in the tracheal tube. The permanent rough edge of the two-bladed tube was very deleterious. At the present time he had two cases under his care in which the children ceased to breathe on removal of the tube. In these the conditions were probably the same as those he had described in 1885. The edges of the tracheotomy wound were grown upon by granulation-tissue. In one case a growth of granulations existed on the posterior surface of the trachea, and this was

removed by Toynbee's ear forceps. He did not think the tube would account either for the absence or presence of granulations. A phlegmonous inflammation occurred in some cases, but he could not say whether this had any share in the causation of the granulations. In many the muscles of the larynx wanted treatment, and he thought that catheterization, which he had practised for some years past, might act by rousing the muscles into proper action.

MR. R. W. PARKER recognized two classes of cases: those with and those without mechanical obstruction. The former far outnumbered the latter. Treatment by catheterization for the cases of mechanical difficulty would not always prove successful. Thickening of the mucous membrane of the pharynx and aryepiglottic folds was an important condition not sufficiently recognized. In the second case he believed that the catheterization proved dangerous by detaching granulations.

In some patients the difficulty remained because the surgeon delayed too long the attempt to remove the tracheotomy tube. He agreed with Mr. Marsh that the tube should be fitted to the case, for the variety in size of the neck, trachea, and child was great. He believed that treatment was not yet entirely successful. Reference was made to a case under his care in a child aged 2 years, who had scalded his glottis, but for whom little could be done at present, though doubtless time would prove of great service, as it had done, in his opinion, in Mr. Pollard's case, for the larynx remained small till about the age of twelve or thirteen, when an extra development occurred, especially in the male sex.

MR. BILTON POLLARD, in reply, could not agree that the pneumonia was due to the trickling down of blood, but believed that it was due to collapse of the left lung, owing to the direction of the tube, which perhaps permitted air only to enter the right lung, for there were no breath-sounds on the left side of the chest whilst the tube was in. The further progress of the third case was not altogether unsuccessful; many granulations about the vocal cords had by treatment developed into cicatricial tissue, there being a sufficient opening through the larynx to permit of breathing for as long as twenty-four hours, when the tracheal tube had to be replaced, apparently because mucus in the trachea became excessive, and the child had difficulty in coughing this up.

IODOL.

SEIFERT reports his experience with iodol in the treatment of laryngeal tuberculosis, and was much pleased with his results. At first he used a mixture of iodol and starch, but when he found that iodol alone produced little or no irritation, the drug was used alone. The patients bore the insufflation of the powder extremely well. The loss of appetite, so commonly seen after the use of iodoform, did not occur, the ulcers rapidly became clean, and the tendency to form scars was scarcely observed. In the case of a man, aged 35, a tuberculous ulceration of the right vocal cord was healed by creasote, glycerin, iodoform and boric acid; an ulcer of the left cord was healed by insufflation of iodoform, and the infiltration was removed by painting with lactic acid; and finally, six months later, a newly-formed tuberculous infiltration and ulceration of the left false cord was healed by insufflation of iodol.

In other diseases iodol was most acceptable because of its freedom from odor, non-irritability, lessening of secretion, and power of disinfection. He had also tried iodol in atrophic rhinitis, after the use of the galvanocautery in the nose and vaso-pharynx, in the treatment of syphilitic ulcers, round ulcers, suppurating buboes, and after opening the pustules of acne.

Internally, iodol was given in a case of sub-sternal struma, 3 grains in pill form, with good results.

To observe the elimination of iodol the writer himself took 8 grains without bad effect.

Iodine appeared in the urine twelve hours after taking, and also in the saliva; the elimination was greatest eighteen hours after taking, and persisted three days.—*Centralb. für Chirurgie*, April 9, 1887.

TREATMENT OF DIABETES.

According to the Paris correspondent of the London *Lancet* (April 30, 1887), DR. LE BLOND makes known another "specific" treatment for diabetes, which, if not precisely new, is novel in its mode of application, and from which he has obtained some remarkable results. The administration of oxygen in the form of peroxide of hydrogen has often been tried, but, although it would seem theoretically to be the ideal treatment for glycosuria, results have not been sufficiently constant to popularize it. M. Le Blond has reopened the

question, and advises the administration of an aerated water which has been manufactured in Paris for the last few years, and which only differs from the familiar *siphon* in that it is gaseous from oxygen instead of carbonic acid. Three cases are reported, in which the treatment caused the total disappearance of sugar from the urine; in a fourth the partial failure was due to imperfect oxidation from chronic bronchial catarrh.

BENZOYL TROPINE AS AN ANÆSTHETIC.

In a search made with the hope of finding some compound that might, like cocaine, possess anæsthetic properties hitherto unobserved, PROFESSOR FILEHNE was induced to turn his attention to the tropeines, atropine having been formerly regarded as a gently acting local narcotic (*Berl. Klin. Woch.*, No. 7; *Med. Rec.*, April, p. 136). By experiment atropine was found to have a slight but distinct paralyzing influence on the ends of the sensory nerves, whilst with homatropine this effect was very decided. Tracing some analogy between the splitting up of atropine into tropine and tropic acid, and that of cocaine into ecgonine, benzoic acid, and methylic alcohol, and ecgonine proving to be inert, Professor Filehne inferred that the anæsthetic property was conferred by the acid radicle. Moreover, he found confirmation of this inference in the fact that just as homatropine stands between atropine and cocaine in its anæsthetic property, amygdalic acid, the acid of homatropine, is in constitution intermediate between tropic and benzoic acids, the acids of atropine and cocaine respectively, as is shown by the following formula:

Benzoic acid, C_6H_5COOH ;

Amygdalic acid, $C_6H_5CH < \begin{smallmatrix} COOH \\ OH \end{smallmatrix}$;

Tropic acid, $C_8H_5CH < \begin{smallmatrix} COOH \\ CH_2OH \end{smallmatrix}$.

Professor Filehne was, therefore, led to anticipate that the compound resulting from the union of benzoic acid with tropine would have a greater local anæsthetic effect than homatropine. This was fully confirmed by experiment, benzoyltropine proving to be a wonderful local anæsthetic, whilst when applied to the eyes it also exercised the action upon the pupils and accommodation characteristic of other tropeines. A number of "benzyl derivatives" were therefore tested, and all proved to produce a decided local

anæsthetic effect, benzylmethyltriacetonal-kamine being the most powerful of those tried, benzyl-quinine came next, and the weakest was benzyl-morphine. This would seem to be a curious instance of a correct deduction being drawn from a false premise, for apparently, of all the compounds experimented with, cocaine was the one which told most strongly against the theory that the anæsthetic rôle is played by the benzoic radicle. If this assumption were correct, benzoyl-ecgonine should have anæsthetic properties, which is contrary to common experience with this decomposition product of cocaine. Dr. Stockman reports on benzoyl-ecgonine (*Pharm. Journ.*, (3) xvi. 898), "the chief action of cocaine, namely, the paralysis of the sensory nerves, is quite absent; in fact, the relationship between the two substances seems to be as profoundly altered by the subtraction of a methyl group as is the case with methylstrychnine and strychnine."—*Pharmaceutical Journal and Transactions*, April 30, 1887.

TREATMENT OF GRAVE EPISTAXIS.

According to the Paris correspondent of the London *Lancet* (April 30, 1887), M. VERNEUIL, who, although one of the most eminent surgeons, makes frequent incursions into the domain of pure medicine, read a communication at the Academy of Medicine upon the treatment of certain forms of epistaxis by counter-irritation over the region of the liver. M. Verneuil began by stating that he had at first thought that the method was entirely his own, but from bibliographical research it turned out that he had been anticipated to a certain extent by Galen, who says that large cupping-glasses applied to the hypochondria arrest nasal hemorrhage. In the first case related by M. Verneuil, the epistaxis was probably symptomatic of cirrhosis of the liver. Quinine, ergotine, and digitalis had all been tried in vain. The hemorrhage continued to recur at intervals. The second patient had suffered from nasal hemorrhage, which seemed to have been caused by the shock of a kick from a horse. In this case plugging had failed. The third was the subject of chronic nephritis, with secondary affections of the heart and liver, and the cavity of the nose had been plugged without effect both with ergotine and perchloride of iron. M. Verneuil's treatment, which was immediately and permanently efficacious, consisted of the application over the region of the liver of a large blister.

ANTIPYRIN IN MIGRAINE.

Antipyrin is best known for its rapid action in the treatment of pyrexia, and it is commencing to acquire a reputation in the treatment of neuralgia. DR. T. S. ROBINSON states in the *Medical Record* for May 7, 1887, that he has a record of over eighty cases in which during the past two years antipyrin was used for the relief of migraine.

These cases are not selected. In fifty-four the drug acted favorably in from thirty minutes to two hours. In fifteen cases the pain was much abated, and when he resorted to chloral, bromides, or other drugs, he had to use smaller doses than the patient had otherwise been in the habit of taking. The relief was greater and the attacks generally cut short. In eight cases it had little or no effect. The reports from successful cases were all in favor of this drug, not only that it was quicker in its action, but that it did not leave the ill effects generally left by other forms of medication they had been in the habit of using. The usual narcotic treatment of migraine is generally hurtful, the patient being too ready, on the slightest symptom of pain, to fly to his favorite drug, many times establishing a habit which is worse than the original disease. This objection cannot be applied to antipyrin, as it neither narcotizes nor stimulates our patients.

He recommends that patients who are subject to attacks of hemicrania should keep powders of antipyrin of 22 grains each constantly on hand, and that on the first symptom of the attack one powder should be taken in a little Vichy water, and repeated in two hours if the pain is not abated.

THE ADMINISTRATION OF CARBONATE OF LIME AS A MEANS OF ARRESTING THE GROWTH OF CANCEROUS TUMORS.

Nearly twenty years ago DR. PETER HOOD published a communication on the value of carbonate of lime in the form of calcined oyster-shells as a means of arresting the growth of cancerous tumors. In the *Lancet* for May 7, 1887, he publishes a second communication on the same subject, in which he states that although his opportunities for employing it in suitable cases have not been large, the results which he has attained through its use have been extremely satisfactory. He refers to several cases in which a persevering use of the calcined shell powder

arrested the growth and pain in tumors undoubtedly of a cancerous character. Dr. Hood urges the persistent and fair trial of this remedy in cases of cancer, where the nature of the affection is early recognized. It can do no possible harm, it need not interfere with other remedies for the relief of pain, its action can be referred to an intelligible and probable hypothesis, and it has been of utility in a sufficient number of cases for warranting us in reposing some confidence in its use.

An advantage of the treatment is that it may be readily prepared at home by baking oyster-shells in an oven, and then scraping off the calcined white lining of the concave shell. The substance thus obtained is to be reduced to a powder, and as much as will lie on a silver quarter taken once or twice a day in a little warm water or tea.

A SIMPLE METHOD OF OPERATION FOR DIVERGENT SQUINT.

Readjustment of the insertion of the internal rectus is now a recognized surgical procedure. It is therefore important that the operation should not only be effectual, but easy of performance and as simple as possible. Since its introduction it has undergone various modifications and is still a very tedious procedure, necessitating the use of an anæsthetic, during the administration of which the patient not infrequently vomits, and matters are thus greatly complicated. The introduction of cocaine has to some extent lessened these inconveniences, but has scarcely enabled us to dispense with the use of an anæsthetic in operations involving the deeper structures.

MR. RICHARD WILLIAMS (*British Medical Journal*, April 23, 1887) recommends the following method as one which will in most cases not require the use of an anæsthetic, and in which the time of the operation may be greatly shortened :

An incision is made in the conjunctiva and subconjunctival tissue over the tendon of the internal rectus, extending from near the margin of the cornea for about half an inch towards the inner canthus. The edges of this incision being separated, the strabismus hook is inserted under the tendon in the usual way, and then confided to an assistant. A curved needle armed with a suitable silk thread is then inserted in the conjunctiva near the margin of the cornea, and carried between the sclerotic and the conjunctiva

towards the muscle behind the hook. It is then passed through the tendon from edge to edge at right angles to the course of its fibres, and brought out at the opposite side of the conjunctival wound. The edge of the conjunctiva at this side of the incision is now raised with a pair of forceps, the needle is insinuated between it and the sclerotic, and brought out near the margin of the cornea at a point corresponding to the point of entrance. It will be seen that the tendon and conjunctiva are included in a single loop. At this juncture the external rectus may be divided or not, according to the requirements of each individual case. This point having been disposed of, the tendon of the internal rectus is divided at a safe distance from the ligature, and the hook is removed. By now tying the two ends of the loop together, the margin of the cornea is brought into apposition with the cut end of the tendon, and the eye is brought into a position of more or less internal squint. Finally, the edges of the conjunctival incision are brought together by means of a fine suture.

The advantages claimed for this operation are : (1) that it is much shorter and simpler than the usual method ; (2) that by passing the ligature in the manner described a very firm hold is obtained both of the tendon and the conjunctiva, which is sometimes apt to tear ; (3) that no anæsthetic is generally required. The objection which naturally suggests itself is that there is a certain amount of tendency to puckering of the end of the tendon where the loop is tied. It would appear, however, this objection is more theoretical than real ; at any rate, Mr. Williams has not found that it jeopardized the success of the operation in any of his cases. Moreover, it can to a large extent be avoided by placing the points of entrance and exit of the ligature at a considerable distance from each other.

HUAMANRIPA.

A Chilian plant, called by the natives huanripa, has recently been reported on by M. Bignon, of Lima, who says that it possesses a deserved reputation as a specific in all diseases of the respiratory tract. It grows only on the slopes of the Cordilleras at a considerable height, and is a small composite plant belonging to the genus *Cryptochaete*. It has long lanceolate leaves, and flourishes from January to May, after which it disappears, although the rhizome remains. It is said to

be very aromatic and resinous. An infusion is used, made from twenty-five grammes of the leaves to a litre of water, which is bitter and aromatic; if made of greater strength it causes nausea. According to DR. ZAPATER, the infusion increases the circulation, accelerates the cardiac movements, and augments the secretions, especially the flow of saliva. In larger doses it causes vomiting, excessive perspiration, diminishes the number of pulsations as well as the respiratory movements, and lowers the temperature. In pleurisy and inflammation of the lungs it seems to have almost a specific effect, according to Dr. Zapater. When it is desired to prevent nausea, a little brandy is given with the infusion.—*Pharmaceutical Journal and Transactions*, April 30, 1887.

THE TREATMENT OF INTRA-PERITONEAL INJURIES.

Abdominal section for the treatment of intra-peritoneal injuries was made the subject of an address delivered by SIR WILLIAM MACCORMACK before the Medical Society of London at its meeting held May 7, 1887 (*London Lancet*, May 7, 1887). The text of the speaker's address was founded on his experience in the treatment of two cases of intra-peritoneal rupture of the bladder produced by external violence. In both of these cases the abdominal cavity was laid freely open, the rent in the bladder closed by suture, and the peritoneal cavity effectually purified. In each instance the patient completely recovered, and two men, the subjects of a heretofore fatal injury, were restored to perfect health.

Injuries of the abdominal viscera may be grouped under three heads,—first, incised penetrating wounds of the abdomen implicating the intestine or other viscera; second, abdominal gunshot wounds; and, third, traumatic rupture of the intestine and viscera without external wound. Of course the great difficulty that besets the surgeon in the management of such injuries is that of diagnosis. These lesions are almost invariably fatal, and the very difficulty of diagnosis imposes upon the surgeon the necessity for clearing up the doubt as to what the nature of the injury may be. It is, therefore, now almost universally recognized that the duty of the surgeon is to explore, first, the wound of the parietes, if such be profound, to see whether it is perforated or not; and, second, examine the abdominal viscera through an exploratory incision to see whether and where they are

injured. Such a treatment is now not only justifiable, but it even may be claimed that a surgeon who, called to an obscure case of severe abdominal injury, or to a penetrating wound of whatever kind of the abdominal viscera, neglects this preliminary operation, is throwing away one of the chances which might have existed for saving his patient's life. An intestinal wound having been discovered, the proper line of treatment undoubtedly is to close it with the utmost care by the Lembert suture, as the one preferred by Sir William MacCormack, after having cleansed the peritoneum and closed the external wound. Already the statistics of the treatment of such cases have shown a successful result in ten out of eighteen stab wounds, while in thirty cases of penetrating gunshot wounds seven have been saved.

In the application of the intestinal suture three conditions are required to insure its successful application,—first, two adequately broad and sufficiently wide surfaces of the peritoneum must be brought into contact; second, the mucous membrane must be excluded, for when the needle passes through the whole thickness of the gut, peritonitis generally ensues from leakage taking place along the line of the thread; third, rapidity of execution is of extreme importance, and that form of suture is the best which can be effectually applied in the shortest time.

In the case of incised wounds of the intestine, if small and if clean cut, the edges of the incision may themselves be sutured together, and where rupture has occurred, or in the case of gunshot wounds in which the intestine is perforated at more than one point, excision of the injured locality is nearly always required. In the case of rupture of the intestine without external wound, exact diagnosis is almost always impossible, and the chief indications for operative interference are varied by the mode of action and the severity of the violence, and the presence of prolonged and profound shock. The duration of the shock is of greater importance than its intensity. A small and quick pulse and hurried respiration, while the temperature remains either normal or subnormal, associated with acutely severe, persistent, and localized pain, increased on pressure, indicate the serious nature of the injury. Bloody vomit or stool, rapid tympany, the evidence of percussion, are inconstant signs, and help us but little. The jejunum and ileum are the portions of intestine most frequently ruptured, and the rent will generally be found just behind the part of the abdomen which has been

struck,—a fact which can easily be verified by experiment. In about fifteen per cent. of the cases more than one loop of intestine is damaged, and in that case the injury generally occurs in superimposed coils. It is difficult at first to distinguish the syncope induced by hemorrhage from the shock caused by a ruptured intestine. In the early period we shall have to arrive at a diagnosis from the nature and violence of the injury and the general condition of the patient. When peritonitis is declared, an exploratory operation is urgently indicated, as collapse comes on very quickly, sometimes very suddenly, and a few hours' delay may negative all prospect of recovery.

Absolute rest has hitherto been the chief indication for treatment. But cases do arise in which abdominal section should be practised, and an attempt made to discover and deal with the visceral wound, arrest the bleeding, and clear away the clots and extravasated blood. We should interfere when we possess a reasonable belief that the intestine is ruptured. We may in some cases properly propose laparotomy as a means of diagnosis, and, indeed, when intestinal rupture is suspected, the operation should be performed at once to afford a good prospect of success. Exploratory laparotomy has no very serious inconvenience, and should be adopted in those cases where there are reasonable grounds for believing the intestine has been damaged, as in no other way can effective assistance be rendered to the patient. At a later period we have not only the ruptured intestine to deal with, but a septic peritonitis, which produces the most profound depression, and often necessitates an undue curtailment of some essential step in the operation, or occasions the death of the patient before its completion. Extreme collapse, a long interval from the time of the injury, or severe coexisting damage to the spleen, liver, or pancreas, of course contraindicate operation. The incision should be made in the middle line in all cases, and at the level which will afford readiest access to the seat of the injury. It is desirable to make it long enough to permit the surgeon to reach without difficulty every part of the interior. According to circumstances, we may then decide to suture the intestinal wound, resect the injured portion of the bowel, or make an artificial anus. The same objections hold in regard to the latter that obtain in respect of artificial anus after gunshot injury. Where it is at all practicable, it is best to finally close the opening in the intestine and also the external wound.

THE ADVANTAGES OF ANTIFEBRIN.

MR. J. K. MURRAY recommends antifebrin as possessing advantages over other antipyretics on the following grounds (*British Medical Journal*, April 23, 1887) :

Antifebrin seems much more powerful than quinine, kairin, or antipyrin. It equals antipyrin in the duration of its effects, and in this respect surpasses quinine or kairin. It is only excelled in the quickness of its action by the external application of cold. Its effects are evident within an hour, and they last from ten to twelve hours when a full dose has been administered. When administered for a long time, the dose must be increased. It produces profuse sweating and redness of the cheeks; it diminishes the pulse-rate, and distinctly increases arterial tension. He found no depressing effects follow its administration, even when full doses were given. Antipyretics belong to two great classes,—namely, those which diminish tissue-metabolism; and, secondly, those which increase the loss of heat. From the sweating it produces and the rise in arterial tension, one might conclude that antifebrin belongs to the second class as well as to the first one. This might explain the quickness of its action, as antipyretics of the second class act more speedily than those which diminish tissue-metabolism.

KÉFIR.

We take from *Le Pratique Médicale*, No. 10, the following account of the preparation and use of this beverage, which in some respects is much like koumiss.

It can be made from the milk of different animals, but it is generally made from cow's milk. Fermentation is excited by the presence of the kéfir, which is a species of mushroom, white when fresh, and yellow when old and dry, compact, elastic, and about one-fiftieth of an inch in diameter.

Chemically it is composed of water, fat, peptone, and nitrogenous material.

Examined microscopically it is composed of the rods and cells of beer-yeast.

It is found in the mountains of northern Caucasus near the snows. The natives believe that it is produced by the bushes which grow upon the mountain-tops. It is probable that the first origin is in the great number of bacteria which circulate in the atmosphere, and whose soil of development is furnished by the curds of coagulated milk.

At the beginning of the preparation of

kéfir the grains should be allowed to swell in tepid water for five or six hours,—2 teaspoonfuls to a tablespoonful of kéfir grains; they should then be washed in cold water and put in half a glass of fresh milk, which is changed every three hours. The grains, which were yellow, become white, and are then ready for the preparation of kéfir.

This is done by placing the white grains in a quart of fresh cow's milk, and the whole placed in uncorked bottles and exposed to a temperature of about 45° F., and frequently shaken. The milk begins to ferment soon, and in seven or eight hours the mass is fermented. The kéfir grains are removed by filtering through muslin, the liquid replaced in bottles, which are only partly filled, and carefully corked.

The milk is left at a constant temperature, and shaken every two or three hours. Fermentation continues in spite of the absence of the ferment, and in twenty-four hours the drink is ready. The grains of kéfir may be washed and used indefinitely.

Kéfir is richer in albumen than koumiss, less alcoholic, and less acid.

The following table of analysis shows the composition of milk, koumiss, and kéfir:

	Cow's milk.	Koumiss.	Kéfir.
Albumen	48	11.2	38
Butter.....	38	20.5	20
Sugar of milk.....	41	22.	20
Lactic acid.....	—	11.5	9
Alcohol	—	16.5	8
Water and salts.....	873	918.3	905

SULPHATE OF SPARTEINE.

M. MASIVS, of Brussels, having been engaged in investigating the physiological effects of sulphate of sparteine, has come to the following conclusions: 1. In small doses it does not modify the carotid pulsations in dogs. 2. In moderate doses it diminishes the irritability of the pneumogastric, accelerates the pulsations, which decrease in amplitude, and at the same time suppresses the periodical respiratory variations. 3. In poisonous doses it induces paralysis of the pneumogastric, also asphyxia, and, as a consequence of asphyxia, a change in the pulsations, which become larger and less rapid, and then quickly smaller and smaller, till they take on the characters of "alternate pulse," and finally cease. 4. The blood-pressure decreases only a short time before death. 5. It exerts in the healthy subject no effect on the urinary secretion. 6. In disease its effect on the heart is uncertain,

as well as its effects on the urinary function and on the subjective condition of the patient. —*The Lancet*, May 7, 1887.

THE EXPLORATION OF THE BLADDER BY THE SUPRA-PUBIC METHOD.

At a recent meeting of the American Surgical Association, DR. F. S. DENNIS read a paper on the above subject. He said the supra-pubic operation of to-day is practically the same as the old operation: the only change has been an improvement in *technique*. The first reported operation was that of Franco, in 1561. From that period to 1879 cases were not numerous, but from 1879 to the present time the operation has been done with such success as to attract attention throughout the world. The time is not far distant when practically the only two operations for vesical calculus will be supra-pubic lithotomy and litholapaxy. Supra-pubic lithotomy is simple in *technique*, safe in execution, free from injury to the reproductive organs, radical in results, curative in application, and brilliant in statistics. The many serious accidents attending the lateral operation are entirely avoided.

Technique of Operation.—For a few days before operation a milk diet should be employed. The day previous to operation the bowels should be moved with castor oil, and on the morning of the operation an enema should be used so as to empty the rectum for the introduction of the rubber bag, and the abdomen should be washed with an antiseptic solution. After the patient has been etherized, the surgeon should introduce a rubber bag into the rectum, above the internal sphincter, into which twelve ounces of warm water are to be introduced. This quantity will have to be increased or diminished according to circumstances. The danger of rupture of the rectum in elderly people and in young boys should be borne in mind. The urine should be withdrawn, and six ounces, more or less, of an antiseptic solution introduced into the bladder. The catheter may be left in the bladder and stopped with cork, and this will serve as a guide to cut upon. The distention of the rectum and bladder increases the distance from the pubes to the anterior cul-de-sac of the peritoneum to three inches. The incision should be made in the median line, and should extend for three or four inches above the pubes. When the transversalis fascia is reached, the use of retractors (on the principle of the eye-speculum) facilitates the operation. Having divided the

fascia, the end of the catheter can be felt and cut upon as a guide. The bladder may then be seized with two tenacula and opened. Where free exploration is desired, sutures are introduced on each side of the incision. The stone is removed either with the fingers or forceps. The bladder may then be washed out. A catheter should be introduced through the urethra, but not left longer than twenty-four hours, on account of the danger of exciting traumatic urethritis. In most instances the wound of the bladder should be left open. In cases of calculi the condition of the vesical tissues is such that primary union is unlikely. In certain other conditions, such as rupture, the wound may be closed, for here the condition is different. The abdominal opening is to be closed and a tube introduced.

The operation is indicated (1) for hard, large calculi, and in persons suffering with paraplegia and deformities rendering lateral lithotomy difficult; (2) for removal of certain foreign bodies, such as hair-pins, etc., or for the treatment of chronic cystitis; (3) in cases of tight stricture, fibroma of prostate, tumors of the bladder; and (4) for rupture. In its extraordinary simplicity, its reduced mortality, its freedom from danger, and its safety for the general practitioner, it compares well with litholapaxy.

The speaker had collected one hundred and twenty-four cases of supra-pubic operation for stone done since 1879. Previous to this date the rate of mortality was thirty per cent. Since then the mortality has been reduced, there being eighteen deaths, a mortality of fourteen per cent. Seven of these deaths may be justly excluded, giving a mortality of nine per cent. According to Sir Henry Thompson's statistics, the death-rate from the lateral operation is twelve per cent.; according to the same authority, the mortality of lithotomy is six per cent. In considering the mortality of this operation, two facts are to be considered. The mortality may be improved by more rigid antiseptic precautions. The second fact is that the operation has been limited to the largest stones. When the smaller stones are included the death-rate will be reduced.

Specimens and models showing the position of the bladder under various conditions were then shown.—*Phila. Medical Times*, May 28, 1887.

CARBOLATE OF MERCURY IN SYPHILIS.

DR. KARL SHADEK, of Kieff, being anxious to try the effects of carbolate of mercury,

which has been strongly recommended in syphilis by Professor Gamberini, requested M. H. Brandt, a pharmacist in Kieff, to prepare some for clinical use. This he did by precipitating a very dilute solution of bichloride of mercury with a concentrated alcoholic solution of carbolate of potassium. A yellowish precipitate was obtained, which, after being frequently agitated with the liquid for twenty-four hours, assumed a whitish appearance. It was filtered and washed with distilled water till the washings showed no traces of chloride. It was then transferred to a fresh filter-paper and dried under a bell-jar. In this way a nearly white, tasteless, amorphous substance was obtained, which was scarcely acted upon or dissolved by cold, but was readily soluble in boiling hydrochloric acid. The name given to it by Dr. Shadek is "hydrargyrum carbolicum oxydatum," and he has been using it in his private practice for several months. At first he gave it in the form of pills, one of which, containing about an eighth of a grain, was ordered three, or occasionally four, times a day. It was well borne, and did not interfere with the digestion. In some cases the treatment was continued for six or eight weeks, without producing colic or other disagreeable symptoms. The total number of syphilitic cases in which it was given internally was thirty-five (twenty-six men, six women, and three young children). In five of these there was swelling of the gums and salivation. Mercury was found in the urine after the third dose. Its therapeutic value was especially remarkable in macular and tubercular syphilides and in syphilitic psoriasis of the palm and the sole. Syphilitic rash and slight relapsing forms yielded to the treatment in from two to four weeks; in syphilitic affections of the mucous membrane, and in papular and pustular eruptions, from four to six weeks were required. Multiple enlargements of glands were but little affected by it. In the case of children from two to four years old, doses of about the fifteenth of a grain were well borne twice a day.—*The Lancet*, May 7, 1887.

THE TOPICAL TREATMENT OF TUBERCULAR PHTHISIS.

The researches of Koch and others demonstrate that bacilli are found in larger or smaller numbers in all forms of tuberculosis, and further, that some idea of the extent of the phthisical process may be determined

from the number of bacilli. It was found that the bacilli are more abundant where there was recent caseous infiltration, and in the interior of cavities whose walls were undergoing rapid softening. When the walls of the cavities are firm and indurated the bacilli are few in number, and they are fewest in the cicatricial contracting and pigmented lung-tissue. By examining the sputa of the phthisical patient much light may be thrown on the condition of the lungs. We may surmise that the fewer the bacilli the less the destruction, and *vice versa*. If we admit that bacilli are the cause of tuberculosis, bacillicides are naturally indicated. The experience of various physicians of the favorable results obtained from the use of bacillicides at any rate warrants their employment, even though they may not admit that the bacilli are the causation of the disease. Many bacillicides have been recommended; among them is corrosive sublimate, and this Dr. J. L. PORTEOUS (*Edinburgh Medical Journal*, May, 1887) in his experience has found to be the best.

Various modes have been suggested for applying the remedies; inhalation of the spray containing the bacillicide being the most effectual, as it gets directly to the part affected and retains the original strength of the solution.

The method which Dr. Porteous employs is to use a spray-producer with a reservoir graduated to hold the exact quantity to be inhaled at one sitting. The patient is then directed to deeply inspire at the same time that the ball of the vaporizer is squeezed. By this means the vapor is drawn directly into the lungs and is in no way diluted before reaching the part affected. This process is repeated every four or six hours. Dr. Porteous reports three cases in which extremely favorable results followed this method of treatment.

THE PHYSIOLOGICAL ACTION OF HYDROCHLORATE OF HYOSCINE.

At a recent meeting of the Biological Society, M. GLEY communicated the results of his experiments on the physiological action of hydrochlorate of hyoscine. A minim of a one per cent. solution of this substance, when dropped into the eye of a dog or rabbit, produced in seven or eight minutes a marked dilatation of the pupil. In man the dilatation of the pupil and the paralysis of accommodation remained nearly five days after the application of one single drop of a one per cent.

solution of hyoscine. The other eye, contrary to what took place in the rabbit, was in no way influenced by the drug. M. Gley recommends the drug on account of the rapidity of its action and its feeble toxic effects; fifteen centigrammes of hyoscine, injected under the skin of a dog, produced no serious accident. —*The London Medical Record*, May 16, 1887.

COLLAPSE FOLLOWING STRAPPING OF THE TESTICLES.

Strapping of the testicles after the evacuation of hydrocele fluids is a procedure which is frequently employed, but which from a case recorded by Dr. J. SMYTH in the *Indian Medical Gazette* for January, 1887, is not entirely free from risk.

Dr. Smyth relates the case of a young man in whom the testicle was lightly strapped and supported after evacuation of the hydrocele. The next day the patient continued well, and as the strapping caused no discomfort the operation was repeated on the right side, which was strapped like the left. The next morning the patient was found in a state of collapse, able to speak only in whispers; he was very pale and bathed in cold sweat, which stood out in great beads on his face and saturated his bedding. The extremities were cold, and the patient complained of numbness of the arms. He pointed to the hypogastric region as the seat of his distress, but did not complain of pain elsewhere. The pulse was small, frequent, and intermittent. The strap-pings were removed and stimulants given, with an immediate relief of the symptoms.

ON THE PRACTICAL VALUE OF OUR PRESENT METHODS OF TREATING THE UPPER AIR-PASSAGES.

The subject was one referred for discussion to the main body by the Section in Laryngology of the New York Academy of Medicine, the discussion being opened by a paper by Dr. Francke H. Bosworth. (*Phila. Med. Times*, May 28, 1887.)

Dr. BOSWORTH said it is now thirty-three years since Garcia demonstrated the feasibility of examining the interior of the larynx during life, and Czermak, availing himself of Garcia's teachings, presented to the medical profession a new method of treating disease and inaugurated a new specialty. He thought it was highly proper to stop for an instant and take an account of what progress had been made in this specialty. The early days of

this specialty were days of instrument-invention, and so rapidly did the number of appliances and ingenious devices for treating diseases accumulate that the impression grew that we treated disease by machinery. Nor was this impression ill founded. Dr. Bosworth thought that when we knew little about the treatment of these diseases our machinery was very extensive. As our knowledge increased the machinery disappeared, until now it might be carried in a hand-satchel.

He then spoke of special methods of topical applications in the treatment of the larynx, lower pharynx, vault of the pharynx, and nasal passages. Although speaking of the treatment of these separately, his conclusions with regard to each were the same: namely, that so-called chronic catarrhal inflammation of the larynx, lower pharynx, and vault of the pharynx was due to disease of the nasal passages; that chronic nasal catarrh was due to nasal obstruction, and the only radical means of relief consisted in removing such obstruction. This was to be accomplished by the use of the knife, saw, snare, or cautery. It was true the spray and the douche had their uses, but in no case had they ever cured chronic laryngitis or so-called chronic pharyngeal catarrh. Their action was only palliative and cleansing. No local applications directly to these parts ever cured such inflammation. It was not claimed for them by anybody that they would cure tumors, syphilis, tuberculosis, or paralysis. He had before said that the lower pharynx was in no sense a part of the air-tract. As he had but recently written on the subject of the surgical treatment of obstructions of the nose, he would now devote most of his remarks to the action of the cautery.

He claimed that the cautery destroyed only the superficial layer of the lining membrane of the obstructed nasal cavity, and that therefore its action in overcoming obstruction was not due to its destruction of tissue, but to its coagulation of the superficial structures, their contraction upon the dilated blood-vessels and hyperæmic tissues, in the manner that a film of collodion acts. This being the case, he claimed that the galvano-cautery was an expensive, especially a cumbersome, apparatus; one which could not be used with delicacy and exactitude; which was not without danger; and consequently its use should be dispensed with and chromic acid substituted. The latter possessed every advantage of the galvano-cautery and platinum wire, and had not their disadvantages.

With regard to apparatus for making spray, he showed a hand-atomizer with a single rubber bulb, which he claimed was as effective as the most costly air-pump and receiver; and, for examinations, a head-mirror two and a half inches in diameter was as good as the more costly.

DR. A. H. SMITH continued the discussion with a brief paper, in which he said there was growing scepticism as to our ability to cure all cases of so-called catarrh of the upper air-passages. Then, referring to the benefit to be derived in the treatment of chronic or sub-acute affections of the lining membranes of those passages by the employment of anodynes and disinfectants, especially by weak solutions of carbolic acid, he pointed out the limitations of such benefits. To show that surgical methods were not indicated in all cases or capable alone of curing diseases of the upper air-passages, he quoted the statistics of certain institutions, going to show that out of thirteen hundred and fifty-one cases only twenty-seven per cent. were considered as calling for an operation. It followed that in over seventy per cent. of the cases other treatment than surgical was required. Any person familiar with the subject must have seen patients with chronic nasal catarrh returning month after month, and year after year, to dispensaries and institutions, having nowhere been able to find complete and radical relief. This was not true alone of the specialty of laryngology and rhinology. The same thing was seen at clinics for diseases of women,—patients returning for months with chronic uterine catarrh, etc. He believed that a change of structure took place; that the vital conditions were altered, and they could not be restored by any measures which we had yet adopted or perhaps would ever discover. In other words, there were certain difficulties and limitations inherent in the case not chargeable to faulty methods of treatment or to want of skill. He had long since ceased to expect, as he had ceased to promise, complete and permanent cures.

DR. WILLIAM H. THOMSON discussed the subject from the stand-point of the general practitioner. In his opinion, the treatment of chronic diseases of the upper air-passages should be directed chiefly by two principles: first, by taking cognizance of cutaneous nerve associations in the causation and perpetuation of inflammation of the mucous membranes; and, secondly, local disinfection.

Organs which were in symmetrical pairs,

such as the hands, feet, ears, and eyes, were so closely associated in vaso-motor relations that the same effect, as far as their circulation was concerned, was produced in both by an impression made on only one member of the pair. Second, there was a close relation between the sensory nerves of the skin and the vaso-motor apparatus of the viscera immediately beneath. Third, there were special relations between the vaso-motor functions of one part of the body and the nerves of sensation in a particular distant part of the body. Wet feet, for instance, might check menstrual flow. This relation also existed between the feet and the larynx, and between the nerves at the nape of the neck and the circulation in the nose.

Unfortunately, we have few vaso-motor tonics. In colds it would be of benefit to apply cold water to the nape of the neck on rising, keeping the hair dry, and to apply cold salt water to the throat. The neck and shoulders should be washed in cold water, dried, and then rubbed with sweet oil. Draughts of air were more harmful than a walk out in the cold air. Exposure of a portion of the surface of the body, especially at night, should be avoided. As to special covering, a thin woollen undergarment should be worn, and over that a perforated buckskin shirt. Buckskin drawers, perforated, might also be worn. He knew of no special clothing so beneficial as this. Chest-protectors, etc., which covered only a part of the surface, were worse than useless.

Speaking of disinfectants and their application in the treatment of diseases of the upper air-passages, he said it was hard to resist the belief, from the evidence already given, that the product of inflammation, as such, was always the result of infection. As soon as a particular tissue began to lose its normal amount of vitality, the enemy (micrococci) found it out and began its work. A practical deduction was that, as the onset of disease could be prevented only by excluding germs, so all chronic mucous inflammations could be got rid of only by driving out such germs after they had obtained access to the tissues. Two methods were to be adopted: first, strengthen the vitality of the parts; second, apply disinfectants directly to the affected parts. The greatest advance, he thought, would be made in the discovery of disinfectants and how best to use them.

DR. H. H. CURTIS had deduced the following conclusions from the observation of a thousand cases of disease of the upper air-

passages. In all cases of nasal stenosis from deflection of the nasal septum, etc., there was subacute or chronic inflammation of the lining membrane of those passages, this inflammation extending also down to the pharynx, and here giving rise to glandular hypertrophy. This affection of the posterior wall in the faucial cavity was due to mouth-breathing, and disappeared on opening up the nasal cavities. Any treatment directed to this glandular hypertrophy without treatment of the nasal passages was without success. Disease of the ethmoid cells was generally due to hypertrophy of the middle turbinated body and consequent occlusion and prevention of exit of the ethmoidal secretions. The treatment consisted in the application of chromic acid to the thickened middle turbinated body in order to reduce the obstruction and allow free access of air and outlet for the secretions. He employed this escharotic to the exclusion of others, and he would be unwilling to exchange it for all the sponges, sprays, etc. Its use was followed not only by clearing up of the nasal passages, but also, in consequence of this, by disappearance of the granulations referred to, of laryngitis, pharyngitis, huskiness of the voice. The chromic acid should be used carefully, but he had not seen any bad results from it. The sooner the profession ceased to apply strong astringent solutions and nitrate of silver to the upper air-passages, and gave proper attention to restoring the respiratory functions of the nasal passages, the sooner would laryngology be placed on a higher plane and relief given to countless thousands suffering from so-called post-nasal catarrh.

DR. W. C. JARVIS thought the spray was undoubtedly of great utility when properly employed. Pound-pressure, he said, meant nothing; but the dimensions of the pneumatic tube and the pound-pressure being given, we had everything. Cocaine would act better, more efficiently, and a less amount would be required when used by the spray than by any other method. Another remedy to be used from the spray was rhigolene, and it was often to be preferred to cocaine, especially where the latter failed to produce anæsthesia. He could not do without the spray for cleansing purposes. The coarse spray possessed nearly all the advantages of the douche. Powders were best applied fine by the compressed-air spray. Iodoform was best tolerated. Chromic acid and nitric acid had their uses. But chromic acid was a treacherous drug. Doubtless it was of benefit in

some cases ; but it should not be used for the relief of hypertrophy of the lining membrane. It was a specific in its action on papillomatous tissue. Regarding the comparative value of surgical with other methods, he thought the decision had been pretty well settled in favor of the former. Where weeks and months were required to cure by local applications, relief and cure came from a single sitting when the snare, saw, or cautery was used. The apparently increased discharge in nasal catarrh was due to accumulation by obstruction, not to hyper-secretion. He spoke of the value of applications of vaseline or other unguents and agents for cleansing and protective purposes.

PYORRHŒA ALVEOLARIS.

MR. NEWLAND PEDLEY, F.R.C.S., read a paper at the Odontological Society upon the above subject. Pyorrhœa alveolaris is characterized by conditions as follows : The mucous membrane, especially that adjacent to the teeth, is deeply congested, tumid, and thickened, and detached from the necks of the teeth and from the roots. A thick, fetid discharge may often be pressed up between the teeth and mucous membrane, which gives to the breath a very repulsive odor. Later, the alveoli become absorbed, and at times more or less denuded, while the fangs of the teeth become coated with a layer of thin, hard, green-brown tartar. Ultimately, the disease progressing, the teeth, one after another, drop out. The pathological changes which take place are hypertrophy of the mucoperiosteal fold around the teeth, accompanied by dilatation of capillary loops, enlargement of the papillæ, and rapid proliferation of epithelial cells. Later the gum becomes firm and contracted, and displays increase of fibrous tissue. The changes which go on in the socket have not been yet satisfactorily worked out, but the examination of the jaws of some carnivora which were apparently affected with pyorrhœa alveolaris would lead to the supposition that there is osteitis of the alveolar process spreading towards the apex of the socket. There are many differences of opinion as to the causes, some maintaining that it is of parasitic origin and due to a specific bacillus, but there is no good proof of this ; others that it is catarrhal, and an extension of inflammation of the mucous membrane ; others that it is due to the irritation of small deposits of hard tartar under the edge of the gum, but this is plainly not the

case, for the disease may be far in advance of the deposit, and in some cases there is not any to be found. It is probably due to some constitutional condition, and the fact that it is often symmetrical, and frequently hereditary, gives support to this view. It occurs in the mouths of patients whose health has been undermined by debilitating influences and injudicious habits of living ; it is a common sequel of malarial fever in America ; young persons recovering from eruptive fevers are sometimes subjects of pyorrhœa alveolaris ; and frequent pregnancies are a fruitful source of the disorder. Attention has been lately drawn to the shedding of the teeth in tabes dorsalis, but it does not by any means seem to be a constant symptom. Mr. Bland Sutton has found that premature loss of the teeth is a very common feature in cases of rheumatoid arthritis in animals, and has also met with it in mollities ossium and other wasting diseases. Magitot, who views the alveolar-dental periosteum as a ligament, and not of the same nature as osseous periosteum, calls the disease symptomatic alveolo-arthritis, and mentions especially as causes chronic Bright's disease and glycosuria, in which latter, he says, the phenomenon is absolutely constant.—*The Lancet*, May 7, 1887.

THE TREATMENT OF MIGRAINE WITH A DOMESTIC REMEDY.

RABON, of Berlin, writes as follows in describing his experience with this treatment in the *Therapeutische Monatshefte* for April, 1887 :

"It is no wonder that against so common and annoying an enemy as migraine an immense array of lauded remedies are advanced. Among these we find some powerful drugs,—nitro-glycerin, amyl nitrite, aconitine, cocaine, and others,—and also many remedies whose application is inconvenient, as massage and electricity. It is furthest from the purpose of the writer to undervalue the effect of these agencies. If a new remedy is proposed the excuse for its introduction must be that it is simple, harmless, and easily obtainable.

"As Nothnagel some years ago reported good results in treating epilepsy with common salt, it occurred to me that migraine could possibly be prevented by small doses of this agent. I accordingly ordered a young man suffering from 'petit mal,' whose seizures were preceded by a well-defined aura, to keep common salt with him, and at the first indication of the aura to take a convenient quantity. The order was followed, and proved successful in every instance. En-

couraged by his success, an aunt of the patient, who had suffered severely for years from migraine, which was preceded by unpleasant gastric sensations, began to take salt to cure her migraine. She took a half or a whole teaspoonful, and drank a little water after it. This treatment was regularly successful when the attack was just beginning, and a fully-developed attack was stopped in half an hour.

"After this case I felt encouraged to try this simple remedy in similar cases, and the results were so good that I feel justified in recommending the remedy. Where the attacks of migraine are attended by symptoms of gastric distress salt is especially efficient, if given promptly.

"My record of cases up to the present embraces only six in whom a positive result was obtained. I hope, however, to attract the attention of others to the use of the remedy. An explanation of the way in which the result is obtained I hope to furnish in the future. Its power in eliciting reflex action seems to me a natural explanation of the effect."

THE USE OF FUMING INHALATIONS IN ASTHMA.

The relief which a well-arranged inhalation affords in the dyspnoea of bronchial asthma is indisputable.

SIR JAMES SAWYER, in the *Birmingham Medical Review* for May, 1887, has prescribed the following fuming inhalation for asthmatic patients with marked success:

R Potassii nitrat., \mathfrak{zss} ;
Pulv. anisi fruct., \mathfrak{zss} ;
Pulv. stramonii fol., \mathfrak{zj} . M.

A thimbleful of the powder placed on a plate is pinched into a conical shape and lit at the top; it burns with a smouldering flame like a pastille, and is held near the patient, who inhales the smoke. The writer states that this method of treating the dyspnoea of bronchial asthma is very marked in its good results in a large proportion of cases. The remedy, however, is only palliative of the asthmatic paroxysms, but it is in these cases that we are often called upon to give prompt relief. For the reduction of the frequency and severity of the asthmatic attacks many other resources are of course favorable in the direction of dietetic, climatic, hygienic, and medicinal therapeutics.

TWO CASES OF RUPTURE OF THE UTERUS; LAPAROTOMY; RECOVERY IN BOTH CASES.

DR. SIMON LEDERER, of Asch, in Bohemia, reports these cases as follows in the *Prager Medicinische Wochenschrift*, No. 15:

In the first a contracted pelvis, whose conjugata vera was not sufficiently shortened to indicate the use of artificial means for completing labor, existed. The patient's general condition and strength were good, and the physician deemed the labor progressing satisfactorily, and left the patient, a primipara, to return in a few hours. On his return, he was informed by the midwife in attendance that the labor-pains had ceased a half-hour previous; the patient was then asleep. An examination revealed the foetus partly in the abdominal cavity, and a hand prolapsed into the vagina. Laparotomy was immediately performed under deep chloroform-narcosis. A large, fully-developed child, with a large head, was removed. The abdomen was cleansed, and the uterus contracted well. A firm abdominal bandage was applied.

Recovery was complete in seventeen days. The entire wound healed by first intention, and but very moderate reaction followed.

Two years later the same woman was delivered, without the services of a physician, of a still-born child, after a rapid, easy labor.

The second case was that of a multipara, who had previously been delivered by the forceps, and had once borne spontaneously after a tedious labor. The pelvic measurements were normal. The uterine rupture was announced by the cessation of the pains and the expulsion of blood from the vagina. As the woman was in good condition, laparotomy was done at once. On the third day after the operation metro-peritonitis set in, which was combated by iced compresses over the abdomen, quinine and opium, free stimulation, and antiseptic douches. Rapid improvement followed, and the wound healed by first intention, except its lower angle, from which healthy pus was discharged, which soon ceased. Nine weeks after the operation, in the absence of the physician's care, the patient ate a large quantity of fresh, ill-baked bread. Peritonitis followed, with great prostration and collapse and death. A post-mortem examination could not be made, and the cause of the peritonitis was not discovered. It is possible that intestinal adhesions had formed, which were broken by the disturbance caused by the ill-digested food.

In the first case the child was found lying

with its back towards the abdomen of the mother, and was easily extracted.

In the second case, the rupture was in the posterior surface of the uterus, and the child was extracted with difficulty.

[The writer makes no mention, in his description of the operation, of suturing the uterus or performing Säger's operation. He seems to have performed the primitive Cæsa-rean section only.—TRANSLATOR.]

HOW SHOULD SANTONIN BE PRESCRIBED TO OBTAIN ITS FULL PHYSIOLOGICAL EFFECT?

DR. K. A. NORDERLING, of Rockford, Ill., communicates the following to the *New York Medical Record*, April 23, 1887: "After the introduction of santonin into the system, the urine will in a short time become of a cherry-red color. Santonin will give the same color when dissolved in an alkaline solution, or when heated to liquefaction with the addition of caustic potash. The drug, therefore, undergoes in the system a change similar to that produced by alkalis and heat. Santonin is insoluble in water and dilute acids, but dissolves in the saliva, the gastric, intestinal, and pancreatic juices. This solution in the gastric juice takes place so rapidly that the maximum dose is completely absorbed in the stomach, as has been shown experimentally by Lewin. But it has also been proved by experiment that santonin, when given in an oily solution, is not at all absorbed in the stomach, but the entire quantity passes into the intestine. It is evident that when the drug is given in powder it will be absorbed and taken up in the circulation before reaching the intestine, and consequently, in order to obtain its vermifugal effect, it must be administered in such a form that it will not be acted upon by the gastric juice. Küchenmeister has shown that the drug must be in solution, as he found that ascarides were not affected by santonin crystals floating in water, but were killed when brought in contact with an oily solution of the drug. In order, therefore, to accomplish its therapeutic object, it is necessary that santonin be in a form in which its vermifugal action can be exerted, and also that it reach the habitat of the parasite. To make the solution, any form of oil may be used, and the best effect is obtained by three grains of santonin dissolved in two ounces of oil, to be taken in four doses. It is also a good practice to add one drop of wormseed oil to each dose, as researches have shown that all ethereal oils

are poisonous to the lower organisms. If a movement of the bowels is desired, castor oil will be suitable, although not in too large a dose, because with strong peristalsis the santonin does not remain long enough in the intestine to produce the desired effect. About two drachms of the oil to each dose will be sufficient."

ALMÉN'S TEST FOR SUGAR.

Of all tests for sugar in urine, Fehling's is undoubtedly the most satisfactory. The only objection that can be urged against it is the difficulty of preserving it a sufficient length of time, so that unless recently prepared it may lead to fallacious results, owing to stale solutions having a tendency to throw down the suboxide of copper spontaneously when heated. This, of course, is a great disadvantage to practitioners, who may be seldom called upon to use the test, and are at a distance from manufacturing chemists from whom they may procure a fresh supply. To remedy this PROFESSOR ALMÉN, of Upsala, has improved the old bismuth test for sugar, and has prepared a solution which has the advantage of keeping unchanged for years, and being at the same time an extremely delicate test for sugar in urine. It consists of a solution of bismuth subnitrate, with caustic soda and potassio-sodium tartrate. In testing for sugar, the albumen, if present, must be first removed by precipitation by heat and acid, and one part of the solution treated with ten of the urine, when, if sugar is present, the bismuth will be deposited in a metallic state. The test is sufficiently delicate to detect sugar in the proportion of only .05 per cent. This test, as we have already said, is chiefly valuable on account of its preservative qualities, keeping well on board ship and in hot climates, though we doubt if it will supersede the use of Fehling's solution, especially as the latter is now supplied in hermetically sealed capsules which preserve the test for a considerable time.—*The Lancet*, May 14, 1887.

NUTRIENT ENEMATA.

EWALD, of Berlin, writes to the *Therapeutische Monatshefte* for April, 1887, his usual methods of preparing such enemata as follows:

In hospital practice an enema may be made most simply by beating up three or five eggs with four or five ounces of a fifteen or twenty per cent. solution of grape-sugar, and this

mixture may be carefully injected, as most convenient. If needed, starch solution, or a mucilage-water, may be added, or, if there exists much irritation, a few drops of tincture of opium. An injection of about eight ounces of tepid water, or solution of common salt, should precede the nutrient enema, and the latter should not be given until the bowel is thoroughly emptied; otherwise the nutrient matter may be at once rejected. Enemata should not be larger than eight or nine ounces, and it is better when this amount is given in two or three doses during the day.

When more elaborate methods can be followed, two or three eggs should be beaten with a spoonful of cold water. As much powdered starch as the point of an ordinary kitchen-knife will take should then be added, and a small cup, or half a large glass, of twenty per cent. solution of grape-sugar, which may be purchased at any chemist's. The whole should be gently heated, and a wineglassful of common red wine added.

The mixture should then be gently stirred or beaten, and the caution should be observed not to heat it so hot as to coagulate the egg albumen. When ready for injection the quantity of fluid should not exceed a half-pint.

If peptones can be easily procured, a teaspoonful of the peptone may be added to the solution of sugar; while advantageous, it is not absolutely needed, for eggs prepared without peptones are easily absorbed.

The enema should be given with a syringe whose terminal tube is long and flexible, or an irrigator, whose rectal tube is large and flexible, may be used. After taking enemata the patient should be kept quietly upon the back, or on the side, for some time.

METHYLAL.

Since the appearance of our issue of April 15, in which we published a summary of the results obtained by several investigators as to the action of methylal, it has been anew investigated by DR. M. MOTROKHIN (*The Lancet*, May 7, 1887). He found that in frogs hypodermic injections of from 0.2 per cent. to 0.3 per cent. of the animal's weight produced more or less profound anæsthesia, which, however, quickly passed away. The lethal dose for frogs was found to be 0.8 gramme. Reflexes were weakened, and with large doses temporarily abolished. Thus, after giving a frog 0.3 gramme of methylal, irritation of the central end of

the sciatic nerve during the period of complete narcosis produced no effect, but when the animal was aroused some reflex activity returned. Irritation of the peripheral extremity of the nerve showed that the drug had produced no effect upon its reflex action. Warm-blooded animals are more susceptible to the effects of methylal than frogs, a quantity equal to 0.25 per cent. of a rabbit's weight throwing it into a deep sleep lasting from one to two hours; with larger doses, loss of co-ordination in the movements was first observed, then the animal fell on its side, and remained in a state of narcosis for from three to four hours, after which it quickly recovered. The lethal dose was 0.45 or 0.5 per cent. of the animal's weight. The irritability of the cortex of the cerebral hemispheres was lowered both by hypodermic injections and by the inhalation of the vapor. Convulsions due to strychnine and picrotoxine in animals subjected to the action of a moderate dose of methylal were diminished in violence, but when the strychnine or picrotoxine was given in lethal doses death was actually accelerated by methylal. Methylal can be employed in the form of vapor for inhalation, or as a liquid for internal administration. When given hypodermically in an aqueous solution of the strength of 1 in 3, it is very painful, and the skin is apt to slough near the puncture. Dr. Motrokhin does not think methylal is likely to be of use in poisoning by strychnine and picrotoxine, except when only small quantities of these poisons have been introduced into the system. Regarding inhalations, two ounces may be inhaled, and only produce in addition to anæsthesia slight headache and dizziness. No experiments seem to have been made with a view to ascertaining the value of methylal as a surgical anæsthetic, but it does not seem to affect the heart's action perceptibly. Prof. Anrep noticed especially that the anæsthesia was more marked on the upper part of the body.

CHOLERA IN PREGNANCY.

DR. QUEIREL, of Marseilles, contributes an interesting article to the *Nouvelles Archives d'Obstétrique et de Gynécologie* for April 25, 1887, in which he reports thirty-five cases which he personally observed, and thirty-two cases whose records have been given him by others,—sixty-seven in all. Of these, thirty-nine died and twenty-eight recovered. Pregnancy was interrupted in twenty-nine, in thirty-eight it continued until the child was

born at term or the mother perished. The conclusions of Dr. Queirel are as follows :

Pregnancy is not a predisposing cause, but increases the gravity of cholera.

We do not know whether cholera is transmitted from mother to foetus; *in utero* the disease is very fatal.

It is a frequent cause of abortion, which does not lessen the severity of the disease in the mother.

The attack of cholera must be of unusual length if the woman does not die before aborting. Abortion from cholera is more frequent in the second than in the first half of pregnancy. A number of such prematurely-born children survive.

A large proportion of children born during the attack of cholera die from the disease in the first few days of their lives. Cholera occurring during the post-partum period is very severe.

The disease destroys lactation if established.

From a clinical stand-point the phenomenon most interesting is severe pain in the vertebral column and about the back.

The mortality among children was seventy-one per cent.

SALOL.

Salol, or salicylate of phenol, has been recently used with considerable success in Germany, both as an antipyretic and local disinfectant. GEORGI (*Berlin Klin. Woch.*, 1887, Nos. 9 and 11) found it useful as a dusting-powder in facial erysipelas; he mixed it with an equal quantity of powdered talc. He likewise employed it locally with advantage in angina, diphtheria, and stomatitis, first making a five per cent. solution in alcohol, and then mixing a small quantity of this with water. In a case of ozæna, the insufflation of a powder consisting of equal quantities of salol and talc every two hours removed the bad odor, though it did not cure the ailment, for he found it necessary to use also astringent irrigations. Given internally, he found it acting beneficially as an antipyretic in phthisis, typhoid fever, acute rheumatism, and other febrile ailments. In phthisis, doses of 7 grains were first given, and then larger quantities, until the effects desired were obtained. He found that 22 grains could be given for a dose, and seventy-five grains in nine hours, without any disagreeable results. In rheumatism it reduced the temperature and relieved the pains. He records favorable re-

sults of its administration in one case of sciatica and three of cystitis.

SEIFERT (*Centralb. f. Klin. Med.*, April 2, 1887) confirms Georgi's favorable report. He used salol as a wash or gargle, in ulceration of the tongue, stomatitis, angina, and diphtheria, first dissolving six parts of salol in one hundred of spirit, and then adding a dessert-spoonful of this solution to a glass of warm water. Seifert also used salol as a powder for insufflation, but he finds it less beneficial than iodol, because, though antiseptic and non-irritating, it does not adhere sufficiently well to mucous membranes and ulcerated surfaces.—*Medical Chronicle*, May, 1887.

EXTREME FREQUENCY OF PULSE AFTER PARACENTESIS.

An interesting case, in which extreme frequency of the pulse followed puncture of the abdomen for ascites, is reported and discussed in the *St. Petersburger Medicinische Wochenschrift* by PROFESSOR DEHIO, of Dorpat. The patient was a man aged 56, with cirrhosis of the liver. In addition to a considerable degree of ascites, there was general œdema and an old-standing hernia, but no heart-mischief could be detected, and the pulse was 86, regular, and of moderate tension. Immediately after the operation the man felt better, and was able to breathe more easily, and a slight rise of the pulse was then noted. The next day the face was pallid, and the patient complained of giddiness and prostration. The radial pulse had become 162, thready, and weaker; the second sound of the heart could scarcely be heard. This condition continued without any great alteration for five days, the pulse-rate varying from 180 to 150. No rise of temperature occurred, and the respiration was about 24. At Professor Kobert's suggestion two milligrammes of coronilin were introduced subcutaneously, which was shortly followed by a reduction of the pulse-rate to 80. A few hours later, however, it rose again to 182. The next day, without any repetition of the coronilin, and indeed without any assignable cause, the pulse sank to 84, and did not again rise to any remarkable extent. From this time, however, the patient's general condition became worse, and he died eighteen days later. The necropsy showed fatty degeneration of the heart and general diffused arterio-sclerosis. There was some hemorrhagic pachymeningitis and a good deal of clear fluid in the ventricles of the brain, the

cerebral substance being of moderate consistence, without any softening and containing less blood than usual. The cerebellum and medulla were in the same condition. The cause of the extreme frequency of the pulse was evidently not the disease of the heart and vessels, as this still existed at the time of death, or eighteen days after the pulse had resumed its normal rate. It must be looked for in the anæmia of the medulla, which doubtless followed the operation. Dr. Dehio proceeds to discuss the question whether this anæmia affected the heart by stimulating the accelerator (sympathetic) centre or by paralyzing the inhibitory (vagus) centre, and strongly inclines to take the latter view, quoting Nothnagel, who, in a recent article, says that when an extreme frequency of pulse is found associated with regularity of the intervals between the beats, a weak cardiac impulse, and an absence of other symptoms, or the existence of such as point to an incomplete emptying of the ventricles, paralysis of the inhibitory apparatus is indicated. Exactly these conditions existed in this case, as shown by its history and the sphygmograms obtained, which were of a hyperdirotic type. Traube has also described a case of this rare condition. An old man, with phthisis, was unable to sit up in bed from the extreme frequency of pulse produced by the anæmia which the upright posture caused in the medulla, which, according to Traube, induced paralysis of the inhibitory apparatus, "the action of which is more easily suspended than that of the respiratory and vaso-motor centres." Another reason given by Dr. Dehio for the view he takes is that it is hardly possible that stimulation of the accelerator apparatus should have been kept up for so many days without any sign of the centre becoming fatigued, the interval between the pulse-beats not having altered at all. The fact was that when the abdomen began to refill the medulla became engorged with blood and the vagus resumed its proper functions. Nothnagel has pointed out the analogy between the sudden loss of regulating power of the vagus, and the sudden loss of consciousness in epilepsy and fainting which is produced by very slight interference with the blood-distribution.—*The Lancet*, May 28, 1887.

IMMUNITY BY INJECTION OF CHEMICAL BODIES.

DR. L. C. WOOLDRIDGE recently communicated to the Royal Society a method by which

he had been able to protect rabbits from anthrax, which is of considerable interest in connection with the general question of the nature of protection in this and other diseases depending on micro-organisms. The method consists in cultivating the anthrax bacillus in an alkaline solution of a peculiar proteid body which can be obtained from the testis and thymus gland. The growth is not abundant, and, after two days at 37° C., it is removed from the culture-fluid by filtration. A small quantity of filtered liquid is injected into the circulation of a rabbit, and the animal can then withstand the inoculation of extremely virulent anthrax blood. The bacillus itself grown in this peculiar culture-fluid has no protective influence; it either kills or it has no effect. The result is extremely curious, for hitherto protection against zymotic disease has been effected by the communication to the animal of a modified form of the disease against which protection is sought. In Dr. Wooldridge's experiments the protection must be produced by some chemical body the product of the activity of the bacillus. The observation belongs to a new order of facts, and appears to fall in with M. Pasteur's theory as to the method in which immunity to hydrophobia is produced by inoculation of the spinal cord of rabid rabbits. Both find some support in Professor Cash's experiments with perchloride of mercury, in which it was shown that after animals had taken a sufficient quantity of the drug, they were no longer liable to anthrax.—*The British Medical Journal*, May 21, 1887.

PATHOGENY OF GASTRIC ULCER.

The precise pathogeny of chronic ulcer of the stomach is one of those undetermined questions which have led to considerable speculation, with comparatively little profit. The position, form, and nature of the ulcer have done more than any positive demonstration of the vascular lesion to favor the current doctrine of its dependence on arterial blocking. But every one knows the difficulties in the acceptance of this view, not the least being the comparative frequency of the disease in the female sex, and the great preponderance of cases where the ulcer is solitary and seated on the posterior surface near the lesser curvature. DR. DECKER, of Würzburg, has the last word on the subject (*Berl. Klin. Wochenschrift*, No. 21), and he advances evidence in support of the initial lesion being traumatic, or rather thermal. Thus, he believes that the contact of hot thickened fluids

with the gastric mucosa excites hyperæmia, which becomes localized, and may lead to venous stasis and hemorrhage in a limited territory, with all the subsequent necrotic changes. He supports his view not only by reference to the clinical history of cases of gastric ulcer (he points to the great prevalence of gastric ulcer among cooks, who habitually test the flavor of their dishes when very hot), but by two experiments on dogs into whose stomach food heated to 50° C. was introduced. In one of the animals a patch of hyperæmia, with hemorrhage between the gastric mucosa and muscularis near the lower curvature, was found; in the other, a deep ulcer of characteristic shape and position had been produced.—*The Lancet*, May 28, 1887.

ACTION OF HYOSCINE ON THE EYE.

DR. O. WALTER, of Dorpat, has published a series of observations on the action of hyoscine on the eye. This body produces some toxic effects very similar to those produced by atropine,—viz., dryness of the throat and dilatation of the pupils; but, unlike atropine, it causes drowsiness and languor; it also sometimes causes nausea and giddiness. Until lately little has been known of the effects of hyoscine on the eye, but within the last few months two other Dorpat students, working under Professor Kobert's direction, have paid some attention to the subject,—one of them, Dr. Sohrt, having published a paper on the general, therapeutic, and physiological effects of hyoscine. Hirschberg and Emmett had, however, remarked the mydriatic action of this subject. Dr. Walter experimented on animals by instilling hyoscine into one eye and atropine into the other, and found that a drop of an exceedingly attenuated solution produced distinct dilatation, acting both on the pupil and on the accommodation much more rapidly than atropine. The dilatation passed off more quickly than that produced by atropine, but the paralysis of accommodation persisted about as long as that produced by an equally strong solution of atropine. No decided effect was remarked on the intra-ocular pressure, but in patients with chronic glaucoma the regular application of hyoscine certainly produced an improvement in the sight and an enlargement of the field of vision. Slight toxic symptoms were produced by two drops of a one per cent. solution. The author recommends repeated applications of a weak solution in preference to a single application of a strong one.—*The Lancet*, May 28, 1887.

THALLIN IN THE TREATMENT OF GONORRHOEA.

According to the Swiss correspondent of the *British Medical Journal*, May 21, 1887, PROFESSOR E. KREIS, of Zurich, has recently carried out in Professor Kleb's laboratory a series of experiments on the influence of thallin on gonococci. He found that a solution of sulphate of thallin of a strength of from four to one-half per cent. completely destroyed the microbes. It may also be mentioned that the drug proved a powerful germicide in regard to the anthrax bacillus and staphylococcus aureus. In view of Dr. Kreis's statement, PROFESSOR GOLL, of Zurich, treated several cases of gonorrhœa, both acute and chronic, with injections of solutions of thallin of various strengths. When given at the beginning of the inflammatory stage injections of a two to two and one-half per cent. solution of the sulphate caused rapid subsidence of the inflammation and quickly changed a purulent into a milky, sero-mucous discharge. In a group of cases seen on the fifth, eighth, or ninth day of the affections, the same injection, repeated twice or thrice a day for six or ten successive days, cured the patient in from eighteen to twenty-five days. The thallin treatment seemed, to a certain degree, to prevent such complications as epididymitis, cystitis, irritability of the bladder, etc. In cases of gleet, Professor Goll obtained good results from irrigation of the urethra by means of a Nélaton catheter, with a one or one and one-half per cent. solution of thallin. Internal administration of the drug in doses of 25 centigrammes every three hours cured a very bad case of gonorrhœal cystitis with epididymitis in five days. In another man, aged 70, long-standing cystitis of gonorrhœal origin was speedily relieved by the internal use of the drug in daily doses of 25 to 30 centigrammes.

THE RELATION OF CERTAIN FORMS OF HEADACHE TO THE EXCRETION OF URIC ACID.

At a meeting of the Royal Medical and Chirurgical Society, held May 23, DR. ALEXANDER HAIG, communicated a paper on the "Relation of a Certain Form of Headache to the Excretion of Uric Acid." Previous papers by the author on the influence of diet in this headache, and its clinical relationship to gout, are referred to. An investigation of the urine was undertaken with a view of testing the relationship to gout. Meat and cheese were taken with the object of bringing on a head-

ache, for purposes of experiment. The relation of this headache to the excretion of uric acid at first appeared equivocal, but definite results were obtained on separating the urine excreted *during* the headache from that before and after. There appears to be retention of uric acid before the headache, excessive excretion during the headache, and diminished excretion after the headache. The excess during balances the diminution before and after; there is no absolute excess of uric acid; hence the previous equivocal results. During a headache there is little or no alteration of the excretion of urea. The relation of the uric acid to the urea is important, and is greatly altered during the headache. When, as the result of *plus* exercise, there is a large excretion of urea and uric acid (though in their normal relation), headache is not far off; and if anything causes the uric acid excretion to fluctuate, headache will be present during its excess and absent during its diminution. This fluctuation in the excretion of uric acid does not affect the urea, is temporary and transient, and there is proof that urates may accumulate while the kidneys are quite sound. The theory which best explains everything in this connection is that of diminished alkalescence of the blood. Does gout consist in a diminished power of forming ammonia to neutralize acids, resulting in a permanent diminution of the alkalescence of the blood? The influence of meat diet and beer in this respect, and the well-known connection of fourpenny ale with gouty deposits, are referred to. A dose of acid, either introduced from without or formed internally, may cause temporary retention of uric acid, and so lead to headache. Beer will do this. Retention possibly does not explain everything, as the excess during the headache appears to exceed the previous retention. There may be temporary excessive formation as well, hence the good effect of salicylate of soda, which diminishes the formation of uric acid. The good effect of a meal on this headache is due to the fact that it increases for a time the alkalescence of the blood. Hence also the good effects of a somewhat vegetarian diet and alkalies in its treatment. The relation here shown between the headache and the excretion of uric acid has an important bearing on the pathology of gout and other diseases connected with uric acid, in demonstrating the way in which temporary retentions of uric acid may be occasioned, and in supporting the theory of diminished alkalescence of the blood, as a cause of these retentions.

MR. G. D. POLLOCK related his personal experience of headache. The urine passed during the attack was always pale and clear. Bilious vomiting used to terminate the attack. Calomel soon afforded relief.

DR. CHEADLE congratulated Dr. Haig on his valuable paper. He doubted, however, whether irregular excretion of uric acid would explain all headaches. Women who were not large meat-eaters suffered from this headache. After railway journeys or anything causing vibrations, the headache could hardly be due to faulty excretion of uric acid. He knew a boy who journeyed from Ireland to Eton and always had a prostrating headache, the result of this journey. The scent of strong flowers—*e.g.*, hyacinth—also caused a headache. He (Dr. Cheadle) also suffered from megrim if for one hour he remained in an ill-ventilated room. A good dose of wine would sometimes cause megrim to disappear, and this seemed to militate against the views advanced.

SIR DYCE DUCKWORTH referred to the two classes of large eaters and drinkers, and those who could not eat or drink to excess without suffering soon from headache and other symptoms. This latter class had a smaller margin for the disposal of excess of food, and he supposed that Dr. Haig belonged to this class. He thought that the author deserved great credit for so painstaking an investigation.

DR. PERCY KIDD was conscious of at least two sorts of headache,—one for which no remedy is useful; the other brought on by obvious causes, and easily relieved by stimulants and other means.

DR. WARD thought there were three sorts of headache, in his own experience. Tiny little chalk-stones from the joints of the hands were obtained at the age of fourteen, when the real megrim began. The nervous headache was probably quite distinct in its causation from that which arises from inspecting a picture-gallery or from excitement. This latter kind may be relieved by a dose of strychnine. Other headaches experienced by him were amenable to sal volatile. Bottled beer is less liable to cause headache, owing to the soda added. A specific gravity of 1030 was also noticed, followed by a copious deposit of urates. Sometimes a decided exaltation of spirits preceded the severe form of headache.

DR. HINGSTON FOX inquired as to the method of estimating uric acid best adapted for clinical work.

DR. HAIG had noticed the light color of

the urine, but this seemed to have no relation to the amount of uric acid. He explained his views of the relation of diminished alkalescence of the blood as causing a retention of uric acid.—*The Lancet*, May 28, 1887.

THE PHYSIOLOGICAL ACTION OF REMISIA FERRUGINEA.

At a recent meeting of the Biological Society, MM. PINET and DUPRAT communicated a note on the physiological action of *Remisia ferruginea*. The forms employed in the experiments were an aqueous and a hydro-alcoholic extract of the root of the plant. Both extracts, as tested by litmus-paper, showed a decided acid reaction. The hydro-alcoholic extract was much less active than the aqueous extract. The experiments were made on frogs weighing thirty grammes, and the dose was the quantity contained in three divisions out of twenty in a Pravaz syringe. A quarter of an hour after the injection, in the foot of one of the hind legs, the animal was found to show general hyper-excitability, with considerable increase of respiratory movement and cardiac pulsation. In some of the animals the energy of ventricular contraction was so great as to produce asphyxia, that continued throughout the entire duration of the intoxication. The heart was found to be abnormally red. Electric contractibility of the muscles remained intact. Ligature of the iliac artery on one side, with injection of the extract into the opposite member, produced no difference in the effect. Section of the lumbar nerves on one side, with injection into the opposite member, caused the convulsions to appear only on the side where the innervation remained intact. When the spinal cord was divided below the medulla, no convulsive action took place. Ablation of the cerebral hemispheres in no way affected the phenomena above described. The authors conclude that *Remisia ferruginea* affects principally the medulla.—*The London Medical Record*, May 16, 1887.

Reviews.

ANÆMIA. By Frederick P. Henry, M.D.

Philadelphia: P. Blakiston, Son & Co., No. 1012 Walnut Street, 1887.

This is a very clear, well-written little book, containing a great deal of information upon the subject of which it treats, an epitome of

our present knowledge, invaluable to any practitioner of medicine who is not thoroughly up with the literature of the day. Simply written, the result of thorough study, we can commend the volume highly to our readers.

The author classifies anæmias as follows:

I. *Primary Anæmias*. Chlorosis, lymphatic anæmia (Hodgkin's disease), splenic anæmia, leucocythæmia, pernicious anæmia. II. *Secondary Anæmias*. Anæmia of fever, anæmia of hemorrhage, anæmia of phthisis, anæmia of heart-disease, anæmia of cancer, anæmia of syphilis, etc. III. *Toxanæmias*. Anæmia of lead-poisoning (saturnine anæmia), anæmia of arsenic-poisoning; anæmia of arseniuretted hydrogen poisoning, anæmia of phosphorus-poisoning, anæmia of nitric oxide poisoning. IV. *Parasitic Anæmias*. Anæmia caused by *Anchylostomum duodenale*, anæmia caused by *Bilharzia mæmatobia*, anæmia caused by *Filaria sanguinis*, anæmia caused by *Plasmodium malarie*.

Careful reading of the latter pages of the book, in which these various forms of anæmia are described, has confirmed us in the belief that we many years ago expressed, that the present divisions of anæmia are unsatisfactory. There can be no such thing as primary anæmia, for anæmia is not a disease, but a symptom or result. The blood does not generate itself, but is produced by various organs, and is subjected to various destructive processes. Anæmia which results either from disease of the blood-making organs or from an affection of the blood-destroying organs, is as much secondary as one which is produced by hemorrhages or phthisis. The imperfection of the popular classification is further shown by the fact that pernicious is stated by Dr. Henry to be very generally the result of the atrophy of the gastric tubules. Therefore, although classified by the author as primary anæmia, it is, according to his own showing, a secondary one. He himself feels this, and attempts to explain the inconsistency, but to our thinking his explanation amounts to nothing.

We are not in making this criticism objecting to the book, which simply is in its view of the subject reflex of the general professional thought of the day. A more original writer than its author appears to be might have attempted to treat of the diseases which produce anæmia, or, at least, would have recognized anæmia as a symptom or result of disease, and classified the forms of it accordingly.

EARTH AS A TOPICAL APPLICATION IN SURGERY. By Addinell Hewson, M.D. Second Edition. Philadelphia: The Medical Register Co., 1887.

In the preface to this the second edition of Dr. Hewson's book, he writes, "It is now issued to meet the demands constantly made for the work, and especially for it as it was originally produced; I have not seen fit to alter it in any respect." The concluding phrase of this sentence may also properly express our view, since we still hold to the same opinion that we did when the first edition appeared, and are not now inclined to alter it in any respect. We continue to think if the results claimed by Dr. Hewson were obtained by the earth treatment, the same and even better results are more likely to be gained by other and less objectionable applications.

CYCLOPÆDIA OF OBSTETRICS AND GYNÆCOLOGY. ANATOMY OF INTERNAL AND EXTERNAL GENITALS, MENSTRUATION AND FŒCUNDATION, NORMAL PREGNANCY AND LABOR. Being Vol. I. of a Practical Treatise on Obstetrics. By Dr. A. Charpentier, Adj. Prof. at Faculty of Medicine, Paris. Translated by Egbert H. Grandin, M.D., etc. In four volumes, two hundred and sixty-seven fine wood engravings, and four colored plates.

New York: Wm. Wood & Co., 1887.

The author aims "to give the practitioner, the student, and the midwife a sufficient, although condensed, knowledge of modern researches." More ambitious than a manual of obstetrics, its author feels sure, from his practical opportunities and his extensive reading, that the Cyclopædia will meet the wants of both practical and theoretical men. The first volume is occupied with, first, a section on anatomy, carefully and thoroughly written, and well illustrated; second, a section on "physiological phenomena," which goes deeply into the mysteries of reproduction, describing even the act of copulation so thoroughly that even the wayfaring man, though a fool, need not err therein, touches upon the question of the production of sex at will, leaving the subject still involved in uncertainty. Describes the process of artificial fecundation, so that any competent person may start out as an artificial fecundator, and discusses fully the topic of sterility; thirdly, a section is given on pregnancy, which, traversing well-trodden ground, will still reward the searcher by some few novel views, and much old and valuable wisdom; and, fourth, a section on labor, which differs but little from the same subject-matter in other obstetric manuals. The illustrations of this sec-

tion are only fairly good; the last, a child being resuscitated in a spirophore, while of indifferent execution, is designed with remarkable spirit.

E. W. W.

CYCLOPÆDIA OF OBSTETRICS AND GYNÆCOLOGY. THE PATHOLOGY OF PREGNANCY. Being Vol. II. of a Practical Treatise on Obstetrics. By Dr. A. Charpentier.¹ In four volumes.

New York: Wm. Wood & Co., 1887.

Vol. II. of the Encyclopædia will prove even more useful than Vol. I. Its range of topics embraces a wider field than the usual one of the obstetric manual. Its first chapter discusses the diseases affecting the pregnant woman, and gives us a mass of information carefully assorted and easy to find at short notice. The relations of cholera to pregnancy, in times of epidemic cholera, are of deep interest. At other times, of course, they are generally overlooked. The author has carefully studied the results hitherto published, and gives us the percentage of miscarriages, delivery, safe retention of the fœtus through the disease, and the infant and maternal mortality. "In the influence of labor on malaria," the author mentions the frequency with which attacks of malaria follow delivery in women not previously affected by the disease.

Scarlet fever the author believes to be almost absolutely fatal to the pregnant woman, though delivery, premature or at term, generally precedes death. In advanced pregnancy he finds measles a very dangerous disease, though more fatal to the child than to the mother. Erysipelas "seems to be less serious than variola." In typhoid fever the danger to the fœtus is occasioned by the high temperature; its peril begins at 104°. To the mother this disease affords more favorable chances than to the fœtus.

While pneumonia forms a very serious complication for both mother and child, pleurisy "does not appear to affect either the course of pregnancy or the life of the mother," except in exceptionally severe cases, and in eighteen cases collected by the author there were but two miscarriages.

In regard to phthisis and influence of pregnancy on it, the author follows and confirms the observations of Gaulard, and believes its influence to be uncertain, sometimes hastening, at times retarding, sometimes causing an apparent outbreak of the disease, and often an apparent cessation of the process. Delivery, however, tends to aggravate, and lactation certainly does aggravate the previously existing condition.

By an evident error the author is made to say that icterus in pregnancy may assume one of two forms,—“the sporadic and the epidemic, or the benign and the innocent.” The author describes what he terms the malignant or grave form. In this form he condemns as bad practice beyond question the production of abortion.

Syphilis and lead-poisoning during pregnancy receive careful attention. Especially interesting is the question of the father's influence when suffering from plumbism at the time of conception. Tobacco also causes the mother using it to frequently abort. No daring man has as yet traced untold evils to a father who is a confirmed user of the weed. Hysteria and epilepsy and the influence of traumatism are discussed, and the chapter concludes with goitre and “ulcerations” of the cervix. For the latter the editor substitutes “erosions,” and adds appropriate remarks concerning laceration of the cervix.

“The Diseases of Pregnancy” forms the subject of chapter ii. The uncontrollable vomiting of pregnancy is studied very minutely. The author has no confidence in dilatation of the external os, but the editor of the book endorses Copeman's method as often of great use, provided the internal os be left undilated. In cases of average severity, but sufficiently grave to justify the trial, the reviewer has seen it beneficial in two out of a number, and in these the relief was sudden and immediate. Between the author and the editor this chapter is somewhat confusing. The author says in regard to dilatation, “We have never obtained any results with this treatment unless it caused abortion;” while on the next page, after describing the treatment of severe vomiting, addressed to the stomach and its assumed dyspepsia, with its high claim for success, he incidentally says, “We cannot accept these conclusions because they do not explain why vomiting should suddenly cease after simple dilatation of the cervix,” a thing which he tells us before he has never found successful unless where it caused abortion, and where the relief could not surely be called sudden.

We especially commend the section on cardiac disease as influenced by pregnancy as containing much valuable thought and sound judgment.

Simple œdema, dropsies, albuminuria in its various forms, and the influence of these conditions on pregnancy, occupy considerable space, and lead up to eclampsia. Under albuminuria the author describes the “albu-

minuria of labor.” Following Dumas and others, he restricts the appellation to a condition antedating labor by two or three days at most, ending with that process, and influenced in its severity principally by the duration and severity of labor itself. This condition he believes cannot only be immediately fatal, but “can become the starting-point of a chronic nephritis.” The treatment for the albuminuria of pregnancy is “to diminish, combat, suppress this tendency to renal congestion, and bring the blood to its normal condition.” To do this venesection is the most powerful means of producing the first result; but purgatives should be first used in “a repeated and constant manner,” whatever that may be; and to meet the latter requisition, while tonics, diaphoretics, and diuretics seem indicated, the author believes them hurtful, and recommends a milk diet, giving a diet table so peculiar that we cannot avoid quoting it.

First day, a quart of milk, with two portions of food.

Second day, two quarts of milk, with one portion of food.

Third day, three quarts of milk, with half a portion of food.

Fourth day and thereafter, four quarts, or milk *ad libitum*, and no food or *drink beside*.

The author, while believing this right in principle, prefers, as we certainly should, to give absolute milk diet at once.

Only in exceptional cases would the author recommend the induction of premature labor. He objects to it mainly because he considers that the strain and effort of labor itself is sufficient to often set up albuminuria, and must, therefore, tend to intensify it if previously existing. In this view, however, he is by no means supported by the most recent writers.

In studying the subject of eclampsia the author leans toward the view of Cohen, of Hamburg, as published in 1875, and considers the condition as divisible into two varieties,—uterine and cerebral, demanding different lines of treatment and differing greatly in gravity.

The author's description of an attack of eclampsia deserves to be read by all. The whole section is evidently the result of great research, study, and personal experience. The editor, in opposition to the author, advises the induction of premature labor as a means of prevention when attacks seem imminent before term.

“The curative treatment of eclampsia” and “convulsions not due to eclampsia” will give

the reader many useful hints in regard to the treatment of these conditions. The early evacuation of the bladder is insisted on, since Lamotte cites two cases in which over-distention of that organ appeared to be the exciting cause. Mechanical and manual restraint is condemned. Even auscultation and abdominal palpation should be avoided, if possible, and still more the vaginal touch, which should never be unnecessarily employed. Of course examinations have to be made from time to time, since the progress of labor is often preternaturally rapid. The methods of treatment are classed by the author as the antiphlogistic and anæsthetic. The former embraces general blood-letting, which the author believes should be moderate and rarely repeated, and which his statistics prove to at least have the power of increasing the interval between the attacks; purgatives, which the author employs, especially calomel and jalap; emetics, which he, with revulsives, has entirely discarded.

Pilocarpine subcutaneously the author considers is as yet a doubtful remedy, since it has not been tested alone to any extent. The editor alludes to the hypodermic use of morphine, but neither editor nor author mention the employment of venesection followed by morphine hypodermically. The anæsthetic method seems about as uncertain in its result as the antiphlogistic method. Still, the author considers it as offering the best hope. Ether he rejects. The difficulty with chloroform he believes to lie in knowing when to give it up. "When the patient has gone several hours without an attack, it is best to withdraw the chloroform a little without giving it up altogether." He says, p. 139, "We think that chloroform acts only on condition that its action is prolonged, and therefore it must be given continuously." Chloral hydrate: the statistics of this drug in eclampsia, as here given, are certainly remarkably favorable. The statistics of Tesbut place the mortality from venesection at thirty five per cent.; chloroform, 17.8 per cent.; chloral alone, four per cent. The chloral, owing to the frequency of emesis, should be given by the rectum. The dose of the author is first 60 grains. If this is not wholly or partly retained, a second similar dose is given at once, and a third if the second is lost. Then, for five or six hours, whether attacks come or cease, nothing more is done, and then another 60-grain dose. This 180 grains is generally the limit, but 240 grains have been given in twenty-four hours. Even when they do not recur after the first dose,

60 grains are again given after twenty-four hours. Wherever labor can be terminated by version or forceps, without injury to mother, it should be done. But with a tight and rigid cervix what are we to do? Leave it alone is the author's advice. The section on convulsions not due to eclampsia deals with neuralgias, nervous troubles from mechanical causes, of central origin, reflex, vertigo, syncope, paralysis, hemiplegia, cerebral congestion, cardiac affections, paraplegia, traumatic paralysis and special paralyses, intellectual disturbances, and is followed by a section on mania and allied disorders.

In treating of pruritus vulvæ the author gives a number of formulæ, but fails to recommend the salicylates, which should always be given a trial. The editor adds a few lines in regard to the benefit often derived from applications to the often eroded os.

Two excellent chapters—on "Diseases of the Womb" and "Diseases of the Fœtus"—are followed by one on "Miscarriage." This, while quite full and abounding in research, exhibits the author's own view in regard to the treatment of this condition, a view in which we think few will coincide. He advocates a perfect let-alone policy in retention of the placenta and membranes. The editor comments in language none too severe upon the dangerous advice given by the author, whose own strictures upon active interference, and especially the use of the curette, are of no gentle character.

But while one may differ at times from the author's conclusions, he at least possesses the merit of giving the reader the premises from which he deduces them, and the reader, with the evidence before him, may come to conclusions diametrically opposite if he will.

E. W. W.

OXYGEN IN THERAPEUTICS: A TREATISE EXPLAINING THE APPARATUS, THE MATERIAL, AND THE PROCESSES USED IN THE PREPARATION OF OXYGEN AND OTHER GASES WITH WHICH IT MAY BE COMBINED, ALSO ITS ADMINISTRATION AND EFFECTS. Illustrated by clinical experience of the author and others. By C. E. Clevinger, M.D.

Chicago: W. A. Chatterton & Co., 1887.

The author has evidently thought much on this subject, and been much vexed at heart, no doubt, at the apparent success of the empiric, who has flourished under his eye like the "green bay-tree." He has watched, perhaps, the "compound oxygen parlor" from its modest beginning in some by-street and humble house to its full development in a truly

palatial edifice, adorned with works of art, flashing by night with electric lights, gilding, and cut glass, and his heart has been seared with envy. The envy of the righteous was the success of the wicked, a feeling as old as the time of David, as old as man, historic or prehistoric. But the author's broodings have led him to investigation. What is it? Does it really succeed? and how? Can any one use it? The affirmative answer to the last question is, if it can be given, the panacea for the envious. They can do it, if they wish. But, then, they do not care to do it. Let the other fellows reap what success they may.

The author is familiar with chemical manipulation, and gives us minute and excellent directions for preparing the gases. Few in active practice could take the time and trouble. The dentist, however, has solved this part of the problem to his own satisfaction and profit.

The author gives us a list of the diseases in which inhalations of oxygen and compound oxygen—oxygen and nitrous oxide gas—are useful. The list is very long. It includes hydrophobia and fatty placenta, septicæmia and ulcers; in short, almost everything; and, after reading it, we are disposed to think more kindly of the advertisements of the present purveyors of this remarkable remedial agent.

Correspondence.

LONDON.

(From our Special Correspondent.)

It seems but the other day that I wrote to you at the beginning of the winter session, and here we are about to commence the summer's work at the medical schools. This is the season appointed in London for the study of pharmacology and therapeutics, the English schools, as a rule, differing in this respect from the Scotch universities, where *materia medica* constitutes a long winter course. If I attempt to give you some account of the teaching of your special subject in London, I fear you will not be altogether convinced of the success that is likely to attend the system. No doubt matters have mended very much in the teaching of *materia medica* during recent years, but still the entire provisions for this course must be regarded as being unworthy of its importance. The more one inquires into this matter, indeed, the more one feels dissatisfied, and the more one sympathizes with our lecturers on *materia medica*, who, as

a class, are known to labor under great difficulties in their efforts to assert a better position for their chairs. In my letters to you I have avoided, as far as possible, committing myself to the present chaos of what with us goes by the name of "medical politics," or that part of medical politics which relates to the State provisions for the proper education, examination, and registration of medical men. I have felt that such a state of affairs as that from which we are now suffering here is never likely to arise with you, and that you may well be spared the infliction of the story of our struggles for reform. But when I come, as I do now, to speak of the teaching of pharmacology in England, I find it necessary to depart somewhat from my rule and to refer to recent changes in the regulations of our examining bodies.

Know, then, that within the last three years an honest and determined effort has been made by our two great royal colleges in London, the College of Physicians and the College of Surgeons, to give in union a single, a thorough, and a complete examination in all medical and surgical subjects, instead of the fragmentary, unsatisfactory tests that were previously in force. New examinations entailed new regulations as to the course of study. Now, however unhappy the confession may be, it is a fact that systematic instruction in medicine at our schools must always be conformed to the demands of examinations. Students must be taught what they are required to know at the examination table, whatever their professors may think. It is hopeless for a teacher with a turn for originality to strike out a new line in his lectures, whether on *materia medica* or on anything else. His students would certainly be rejected, and he would soon find himself compelled to return to the beaten track of the college schedules. Reform, therefore, must begin with the examining authorities. The lecturers have to use their influence with the examining boards to secure proper regulations and then teach up to them. But here comes the rub. What does the influence of modern pharmacology with us amount to? How were our lecturers on pharmacology to obtain anything like a reasonable recognition of the importance of their subject from the venerable heads of the venerable colleges? What could be expected in this direction of public men who were mainly educated in the days when instruction in pharmacology began with a mass of botanical, geographical, and chemical details, and ended with a col-

lection of empirical cut-and-dry applications of drugs known as their "therapeutics"? The difficulty would appear to have been to bring the heads of our examining bodies to understand that there is such a subject as pharmacology, relating to the action of drugs on the healthy body, quite apart and distinct from medicinal therapeutics, the treatment of disease with remedies.

However, difficult matter as it must have been, the colleges have been induced to take one step in reform which is of the first importance. Although they still cling to the phrase "medicinal action" in their requirements of students of the first year, they have separated *materia medica* from therapeutics in the examinations, the second subject not being required of the candidate until his final appearance before the board, when it is taken with medicine, surgery, and midwifery. For this great improvement the colleges deserve all credit.

Now let us inquire how our lecturers have taken advantage of these new and better regulations. I regret to say they do not appear to me to have availed themselves of the reform for which they agitated. The plan on which many or even most of them seem to deal with their subjects appears to me to be far from satisfactory. Whilst they agitated, as I have said, for a distinction between pharmacology and therapeutics in the examinations, I question how many of them, to judge by the accounts that reach me, have divorced the ill-matched pair of subjects at the schools. I fear that a course of *materia medica* and therapeutics in the average London school of medicine still consists of an hour's systematic lecture four or five times a week, an occasional demonstration by the lecturer or his assistant of the physical characters of the principal drugs, and a general superintendence of a class in pharmacy in the hospital dispensary, of which the student may or may not avail himself. To begin with, the time devoted to the whole course—some forty hours, from first to last, in the way of lectures—is ridiculously short. But the improvement that appears to me to be most urgently demanded is what I have just called the divorce of *materia medica* from therapeutics. The time has surely come for us to cut these subjects clean apart and give them to different lecturers. It is not only that professors like Dr. Lauder Brunton and Dr. Frederick Roberts might well be released from the drudgery of *materia medica*, but that the knowledge of men of their learning and experience ought

to be turned to very different account in the direction of a thoroughly practical course of therapeutics. But I must not be unjust. I understand that at some of the smaller hospitals a beginning has actually been made of the kind I have indicated, and that their senior students will now have an opportunity of listening to lectures on general therapeutics concomitantly with their work in the wards. It is certainly but a question of time, the establishment of instruction of this kind in all our schools of medicine.

Before I part with this subject let me tell you that the hope has been realized which I expressed to you in my letter of December, of the establishment of the Croonian lectureship on a basis favorable to therapeutics. The College of Physicians has now made the final arrangements for the future disposal of the trust money. This will amount to the handsome sum of over two hundred pounds a year, one hundred guineas of which will be paid to the lecturer, whilst the balance will be devoted to defray the necessary expenses.

I will pass on now to a question of treatment of a very different kind. No doubt American practitioners are aware that our government appointed a committee, a good many months ago, to inquire into the value of Pasteur's method of inoculation against hydrophobia. There was something like a hydrophobia scare in England most of last year, which had its origin not so much in the actual increase of the disease as in the severe restrictions with regard to muzzling dogs which were enforced by the London police, and which roused popular feeling to a wonderful pitch, fortunately in vain. The government committee is a very strong one, including as it does Sir James Paget, Sir Joseph Lister, Sir Henry Roscoe, Dr. Quain, Dr. Burdon-Sanderson, Dr. Brunton, Mr. Fleming, and Mr. Victor Horsley acting as secretary. The task of the committee is undoubtedly difficult,—to pronounce an opinion on the Pasteur system which shall be a practical guide to the authorities in this country. We need not be surprised, therefore, that so far no report has been issued. The committee might at once have hastened to express an opinion on the subject, but such an opinion could manifestly have been of a preliminary character only, and most probably would have been erroneous and misleading. Not only must the results of this as of every other method of treatment be weighed with the greatest care and caution, but in this particular instance so-called results could be of no

possible value until a period of many months had elapsed after the application of the remedy,—until, in a certain number of test cases, at least the average period of incubation of hydrophobia had been passed. However, I hear on good authority that we may expect a report shortly. The committee has not been idle. Mr. Horsley has studied the method as well as the records in M. Pasteur's laboratory. He has been provided with a list of various series of cases of bite that have been treated in Paris. On the results of their inquiry into these series the report of the committee may be expected to be distinctly favorable, as well as on the results obtained by evidence of other kinds. I understand that the committee have arrived at the conclusion that the percentage of deaths from hydrophobia after bites of rabid dogs is decidedly lower in inoculated persons; that the system has been proved to be protective. With respect to possible danger from inoculation, I must refer to a fatal case of Landry's paralysis, or acute ascending spinal paralysis, which occurred here in one of Pasteur's patients, and caused considerable discussion at the time. The patient in question, who was an attendant at the Brown Institution for the Study of the Diseases of Animals in London, had been bitten by a rabid cat, in which Mr. Horsley, the professor superintendent, was studying rabies. The man had been at once sent to M. Pasteur, and treated with *intensive* injections, but he died with perplexing spinal symptoms immediately on his return from Paris. Whatever may have been the exact nature of his illness, there was a general impression among the profession here that the patient died from the effects of the inoculation, as a few other cases appear unfortunately to have done. However, risk will probably disappear under the milder injections now used.

It is most sincerely to be hoped that the favorable report which I expect from the committee may bear the test of time. Were it only for Pasteur's sake, one would rejoice to see the value of his method accepted. From first to last he has been a pattern of generous, open, kindly dealing with regard to it, receiving strangers from every country with the greatest possible attention and consideration, laboriously treating half a hundred patients every morning, and entirely declining to accept any remuneration or other return than thanks for his trouble, even from those who were in the best possible position to pay for his services.

PARIS.

(From our Special Correspondent.)

The Paris Faculty has of late been paying a heavy tribute to death. Barely more than three months since Professor Bécларd was carried off by acute pneumonia. Next Professor Gosselin, the celebrated surgeon and scientific successor of Velpeau, succumbed on April 30, a victim to a cardiac affection of long standing. And now we have to record the death of another professor of equal renown, but younger than either of them. A. Vulpian, a native of Paris, like his two brother professors, died on May 18, after a short illness from infectious pneumonia contracted at the dissecting-table. He was born in 1826, graduated in 1854, and became a Fellow (*agrégé*) of the Faculty in 1860, with a remarkable thesis upon Secondary Pneumonias. After being a physician of the Salpêtrière and Pitié Hospitals, his researches on the nervous system caused him to be chosen, in 1867, for the chair of pathological anatomy at the Paris Faculty of Medicine. A bitter campaign was made against him by antagonists, who accused him of atheism and materialism. At the time—under the empire—such doctrines were not favored; but now, under the third republic, they rather lead to preferment. It is hardly necessary to add that the charge was neither proven nor even answered, and Vulpian was the medical attendant of the Comte de Chambord (Henry V.) during the last illness of the champion of the right divine and papal supremacy. Dr. Vulpian became a member of the Academy of Medicine in 1868, of the Academy of Sciences in 1879, the President of the Faculty in 1875, and the Perpetual Secretary of the Academy of Sciences in 1885. His labors as an investigator were chiefly directed towards the anatomy and physiology of the nervous system. Among his published works are his "Lessons on the General and Comparative Physiology of the Nervous System," "Lessons on the Vaso motor Apparatus," and "Affections of the Nervous System." Professor Vulpian was justly esteemed for rigorous method and exactness of observation as an investigator and keenness of diagnosis as a physician. He was a most ardent supporter of Pasteur's theories, and the one who decided him to attempt for the first time on man inoculations with attenuated rabic virus.

But though professors and scientists may die, the field of science in Paris hardly looks likely to run to waste owing to the lack of workers, as may be seen from the gleanings

below. To begin with therapeutics, methylal will be the first noticed.

Methylal as a Hypnotic.—Methylal is a substance comparatively long known to chemists as one of the products of the oxidation of methylic alcohol. It is an ethereal liquid boiling at 42° F., smelling like acetic ether, and soluble in three times its weight of water. Messrs. Mairét & Combemale have been studying its physiological and therapeutical actions, and now offer it as a new addition to the list of hypnotics, after presenting its credentials in several communications to the Academy of Sciences. Experiments were first made on animals to investigate the physiological properties of the chemical, its doses, best way of exhibiting, etc. It was found that no matter how administered, hypodermically, by the lungs or the stomach, methylal acts as a true hypnotic, and the more so that the animal operated upon is nearer to man. A monkey, for instance, is set to quiet sleep with half the dose necessary for a dog or a cat, while guinea-pigs pass from a somnolent to a half-comatose state, according to the dose, without ever enjoying real sleep. The proper method of administering the chemical is through the stomach. Hypodermic injections are quite painful and apt to produce ulcerations; inhalation or pulverization are irritating to the lungs and nasal membranes. On the contrary, the ready solubility and far from unpleasant taste of methylal render it easy to administer in any ordinary potion or mixture, although the effects are not so rapid as with the two other modes, especially the hypodermic, but they are more persistent.

On man methylal acts as a hypnotic, and seems to be more particularly adapted to certain forms of dementia. It was tried with thirty-six insane patients suffering from nervous agitation and insomnia. In all cases it was given immediately before retiring, at one dose, in an ordinary potion (*julep simple*). The patients never showed any repugnance to the medicine, nor was any organic trouble caused by its use continued for some time. The following are the particulars of its effects in the different forms of insanity. In incipient madness (*folie*) methylal has no hypnotic action, even when the dose is increased to 7 and 8 grammes ($1\frac{3}{4}$ to 2 drachms), but during the periods of acute agitation it generally succeeds at first in procuring sleep in doses of 5 or 6 grammes. The effect, however, wears off in from three to five weeks, even when the dose is increased. The same is true with patients suffering from simple dementia. In

alcoholic mania methylal is unsatisfactory, and is not recommended. In dementia from atheromasis small doses of 3, 4, and 5 grammes procure sound and continuous sleep for the first five or six nights, but after this period, even with increasing doses, the sleep, as in simple madness, becomes less thorough, and lasts only some five or six hours. It is in paralytic dementia, at its different stages, that methylal gives, as a rule, the best results, in doses varying from 5 to 8 grammes. It is also in this form of insanity that the medicament keeps its power for the longest period without an increase of quantity. The *julep* or *potion simple* of the French Codex, alluded to by Drs. Mairét and Combemale, is made as follows :

Simple syrup, 30 grms. (1 ounce);
Orange-flower water, 20 grms. (5 drachms);
Distilled water, 100 grms. (3½ ounces). M.

The methylal is administered simply dissolved in the mixture, but it must be borne in mind that in all cases the quantities indicated must be understood by weight, and not by measure. With a liquid of sp. gr. 0.8551 like methylal, a fluidounce is quite different from a troy ounce.

To conclude with methylal, it appears to possess exclusively hypnotic properties. Its effects on the brain are transient and leave no depression. Even after being administered for fifteen consecutive days, no troubles of nutrition, of the general functions, or of the nervous system were observed. For these reasons, notwithstanding its relatively weak power, methylal is recommended as a safe and reliable hypnotic in some forms of insanity.

Elimination of Formiates.—The chemical similarity of formic and acetic acids might lead physiologists, *a priori*, to think that formiates are most likely decomposed in the economy in the same manner as acetates are, and in the same way are eliminated as carbonates. But experiments carefully made by Drs. Gréhan and Quinquaud prove that the combinations of formic acid show in the economy a resistance to decomposition quite unexpected to chemists. The most difficult part of the investigation was the estimation of formic acid. In the absence of a better method, Drs. Gréhan and Quinquaud were obliged to employ the distillation process, *in vacuo*, in the presence of an excess of sulphuric acid. Analytical chemists, who like nothing so well as a readily-collected precipitate, know the tediousness and difficulties of

distillation processes. But it seems there is no choice in the matter. Experiments made upon dogs, frogs, and pups show that when ingested into the stomach, or injected into the blood, *formiate of sodium* passes off mostly through the urine, without the slightest decomposition. No excess of carbonates is found in the urine during the administration.

Ether-drinking is almost unknown in Paris, the natives having as a rule no propensity for intoxication of any sort, although the trade in wines and liquors is as free as that in tea or ready-made clothes. Whether such freedom is the cause or the result of moderation in drink is a question that may be left to moralists to decide. However it may be, a case of *ether-poisoning* reported by Dr. E. Ory has attracted notice, owing to some of its features. The patient, Mr. X., is a Japanese, age 35, of small stature, spare, and very nervous. Being a dyspeptic he began, to ease his pains, to inhale ether; then to take from time to time ten drops or so in water,—so runs his story,—and finally one day, for some reason or other, he swallowed at a dose a quantity of ether not exactly ascertained, but in no case less than fifteen grammes (half an ounce by weight). After this draught, mixed by himself with sugar and water in a café, he took a cab and drove home. Judging from the distance, at least half an hour must have elapsed before he could have reached his rooms. There his wife only noticed he was somewhat strange, acting like a man slightly inebriated; when, after sitting a short time, he suddenly ceased to speak, and fell into a comatose state. From red his face turned pale, he vomited some aliments, and fell into a syncope. The ether had been swallowed at 4.30, the syncope occurred at 5.30, and it was 6.30 before Dr. Ory could reach the patient's bedside. The diagnosis at first was somewhat perplexing, when, on attempting to induce artificial respiration, the smell of ether, hitherto covered by that of the ammonia, vinegar, etc., used by the attendants, became distinctly recognizable in the mouth, and gave a clue to the cause of the swooning. There was no longer any hesitation as to the treatment,—the usual one in such cases. Rough frictions were ordered, the windows opened, and artificial respiration was resorted to. An enema with 8 grammes (2 drachms) of acetate of ammonium was prescribed to ward off a relapse of the prostration. Not to enter into all the details of the treatment, suffice it to say that after a short amelioration the physician was called in again, and had to

resort again to artificial respiration. The total duration of the anæsthetic sleep was twelve hours, and of the phenomena depending upon the action on the medulla,—abolition of the respiratory and heart movements,—four hours. During several days the urine was more or less abnormally colored, intensely dark brown at first, and gradually toning down to the natural hue within about four days. The icteric coloration of the skin and sclerotic, manifest at first, slowly passed off also in some ten or twelve days, when the patient resumed the orthodox Japanese color. A persisting congestion of the lungs was also observed. The patient kept his bed for fifteen days, and, owing to extreme and obstinate anæmia, had to remain in-doors for three months and a half before going out for the first time. Dr. Ory, agreeing with Dr. Morewood, of Draper's Town, thinks it was artificial respiration that saved the life of his Japanese patient.

Physiological Effects of Earthquakes.—At a recent meeting of the "Société de Médecine Pratique," an association composed of both physicians and pharmacists practising in Paris, Dr. Duchaussoy related his medical experience with the peculiar effects of the late earthquakes at Nice, Cannes, and Mentone. Among the immediate consequences he noted three cases of metrorrhagia, one of which occurred in a woman who had ceased to menstruate four years before. Sea-sickness he found quite common. Several women became suddenly insane; but one who had been ailing six months from paralysis was cured immediately. Patients with heart-diseases suffered most, many experiencing violent fits of palpitation, while several sudden deaths were recorded. A few ladies who bravely stood the morning shocks had a violent fit of fever in the evening.

The consequent or secondary effects were no less striking. A vague feeling of dread was common; many persons could not go into their bedrooms in the evening and lie down for the night. Some had for days a periodical recurrence of the trouble experienced during the earthquake, a recurrence accompanied with copious perspiration, loss of hair, failing appetite, and extreme weakness. One, especially, a lady, more than thirty-five days after the accident, was still so affected that she could not see a piece of furniture oscillating without great involuntary terror. Dr. Brochin's opinion was that the case of paralysis, quoted by Dr. Duchaussoy, was probably of hysteric origin, as he (Dr.

Brochin) had occasion to observe an effect just contrary in an hysteric young woman who had experienced no fits for several months, and in consequence of the earthquake was taken afresh with numerous fits following one another. Dr. Ley finally related a case of sudden death from heart-disease. The patient, a lady, would certainly have lived longer had not the emotion caused by the earth trembling brought her case to an abrupt termination.

Tuberculosis from Whey and Cheese.—That the milk of cows affected with phthisis may propagate the disease among the consumers is a fact now generally admitted. But M. V. Galtier goes a step further, claiming that even the whey and cheese made from such milk are liable to communicate tuberculosis. In a memoir presented through Dr. A. Chauveau to the Academy of Sciences, he has marshalled quite a convincing array of experiments upon rabbits and guinea-pigs to prove the dangerous nature of such aliments. Not that he followed the long and tedious process of feeding the animals with the products. He simply inoculated them with small quantities made from milk known to be contaminated, and thus caused unmistakable tuberculosis, even with cheese that had been made for over two months. From his experiments he has come to the conclusion that germs of tuberculosis are to be found not only in the fresh milk of cows affected with phthisis, but also in the dairy products derived therefrom; the germs remain both in the curd and the whey; so that man can most likely contract tuberculosis from the fresh milk as well as the curd, the whey, and the cheese even salted, which proceed from a consumptive animal. Poultry and swine fed with buttermilk of like origin are also liable to become phthisic, and to such cause the disease in farm-yard animals may in many cases be with reason attributed. Finally, the milk produced by cows suspected of tuberculosis should in no shape be used for human consumption, but only for feeding animals, and even then after thorough ebullition.

PARIS, May 21, 1887.

BERLIN.

(From our Special Correspondent.)

During the week immediately following the Easter holidays there occurred two of the most remarkable Congresses for German medicine,—the Congress of the German Surgical Society in Berlin and the Congress of

the Society for Internal Medicine in Wiesbaden.

If I were to attempt to describe the amount of material which appeared and was discussed at these Congresses, the choice would be most difficult, as it would be impossible to confine all that is instructive and interesting within the narrow limits of a letter, and I cannot think your readers would be satisfied with only a description of the themes under discussion. I therefore prefer to make a selection of those which seem to me most suitable for your journal, giving them a thorough report and only touching lightly upon the others.

The German Surgical Congress has had fifteen meetings before this one, and a large part of the history of surgery owes its existence to the transactions of these meetings. We see the great change brought about in surgical practice by the theories of Lister, and the German Surgical Congress has not only had the greatest influence in the development of these theories, but the rapid adoption of them is less Listerism than the skilful absorption of them by such men as Volkmann, Bardeleben, Thiersch, Esmarch, and others.

The Surgical Congresses of seventy years bear testimony that the Lister system, as well as operative surgery, owes to them its greatest development. Nearly every German Surgical Congress has produced some remarkable progress, the entire completion of which we have not yet reached, but this tradition has not been sustained by the impression made upon us by the meeting this year; there seemed to be something lacking. It is true there were many cases discussed, but there failed to be anything decisive upon any question. The only subject which led to a discussion of great value was the treatment of peritonitis by laparotomy, but which had no satisfactory conclusion; that, however, was in the nature of the case. We will not leave this subject, however, without mentioning the vindication of iodoform as an antiseptic, in spite of the attacks made recently upon this valuable remedy by the Danes Heyn and Rovsing. Not only were good practical results testified to, but theoretical experience refuted the objections made by the above-mentioned authors. We may, therefore, rejoice that this medical treasure remains as a valuable remedy, of which, unfortunately, there are only too few.

If we confine ourselves to a short account of the proceedings of the Surgical Congress, on the other hand we must be more diffuse in our account of the Congress for Internal Med-

icine. This Congress was established in 1881 through the influence of Leyden, and received from the beginning an organization which guaranteed its importance for the future. The principal object of the meetings is the general discussion of important questions upon internal medicine, as far as they are known, that an opinion may profitably be obtained. These discussions are most carefully prepared. Two authorities introduce a given subject, and as it has become the custom to hear the opinion of every competent authority upon the matter under discussion, a really exhaustive decision is obtained, as not only the most celebrated physicians of Germany, but also of other countries, regularly attend the Congress. We can, therefore, assert that this Congress is the heart of the scientific research in Germany.

There were three subjects under discussion at the Congress this year. One, the localization of diseases of the brain, we shall not describe, as it does not come within the scope of your journal. The second subject, the pathology and therapeutics of whooping-cough, was decided by all to have made no advance that was at all remarkable during the last twenty years. The third subject was the therapeutic treatment of phthisis, and on this subject we will speak more particularly.

When the Congress met for the first time five years ago, it was most natural, from the effect of the discovery made not long before of the tubercle-bacillus by Robert Koch, that there should have been a discussion upon the results his discovery would have upon the treatment of diseases of the lungs. The great importance of Koch's researches upon the etiology and diagnosis of tuberculosis was unanimously recognized then. Since that time there have been a series of attempts to derive some benefit from them for the therapeutics of consumption. Only too soon one had to realize the fact that to attack the tubercle-bacillus with substances fatal to the bacillus in the human body was impossible, because all these substances destroy the living cell in which the bacillus has its place. This fact, therefore, was unanimously established this year by the Congress,—*there is no specific remedy for pulmonary consumption*. All medical treatment can only be against certain symptoms of this complicated disease. For the actual cause of the organized disease there is no cure.

Apart from the negative result arrived at, the general knowledge of this fact would save many diseased from much suffering from the

application of all kinds of useless medicines could it be proved that the discovery of the tubercle-bacillus had been without benefit therapeutically. This, however, is not the case. On the contrary, it has made it possible to institute in another direction careful investigations for a rational treatment of consumption, and especially for prophylactic treatment of phthisis.

If we take the position of endeavoring to prevent the spread of phthisis from the standpoint of the tubercle-bacillus, in its relations as a living organism, as the cause of this disease, the solution of the problem may be attained in two ways: we may endeavor to destroy or render inert the noxious agent itself, or we can give all our energies to preventing its entrance into the human organism.

The first undertaking comes within the province of hygienic science in its widest sense; the disinfection and care of buildings, lodgings, food-stuffs, clothing, all afford a field, the limit of whose relationships it is hard to define; but as prophylactic and disinfective measures have given such good results in other fields, we should never lose sight of the possibility of like success in the prevention of this greatest scourge of humanity:

In the hygiene and prophylaxis of the individual we have efficient means to prevent the direct transference of tuberculous poison. The prohibition of intimate association with the phthisical in the act of kissing; the disinfection of the sputa; the careful cleansing of soiled clothing; the careful segregation of such patients,—all these precautions are ordered, unfortunately, by but an occasional physician. And at present a successful protection against phthisis may be said to have been more commonly accidental than the result of intelligent effort. The transmission of tuberculous poison by the media of tuberculous meat and milk has been clearly demonstrated; and hence the necessity of careful supervision of slaughter-houses and a thorough examination of meat.

We come now to the second question, How can we prevent the entrance into the human body of the cause of phthisis? Now, those must be considered who inherit the tendency to phthisis, and sooner or later will be liable to have it. It is just these who are to be protected, even before their entrance into the world, from the slightest chance of infection, by preventing their being nursed by phthisical mothers or wet-nurses, sleeping with phthisical persons; the care of such children by phthisical attendants and servants is to be

strictly avoided. Through careful nourishment the resistance of the body is increased, and the choice of an occupation which will allow being much of the time in the open air is of the greatest importance. Among all these prophylactic measures there are many which can be carried out with a fair hope of success, and we need not sink helpless before the enemy. But when, in spite of every effort and care, the disease has penetrated into the organism, in spite of the above assertion that there is no medicine known which will cure phthisis, we must not feel hopeless for those who are already invaded by the poison. To the question, Can phthisis be cured? there was no contradiction. It cannot be denied that the sacrifices are great with which the cure must be bought. For the very reason that recovery is possible, the physician must inform his patient of the seriousness of his condition. The first thing necessary is the hearty co-operation of the patient; then the slightest deviation from the mode of life prescribed lessens the probabilities of permanent cure. To attain this the *hygienic dietetic* method was recognized by all. The details of this method must be determined by the physician and the circumstances of the patient. Fresh air, protection against taking cold by rational clothing and care of the skin, a regular diet. In the latter great caution against overstepping the prescribed rules. The doctrine that some places are, geographically and geologically, better adapted to consumptives than others, was not received without contradiction from the opposite side. A strict treatment in an institution was almost unanimously recommended for those liable not to persevere in a strict course of cure. Those patients, however, who are able to seek a favorable climate, or who can afford care in an institution, belong to a very small class, and the number of those persons of small means and the very poor is very large, therefore there is a great necessity for more consumptive hospitals. The care in an institution, which might be situated either near a forest or in the middle of a large garden, would combine many of the requisites to a cure. Surely a great blessing would attend the sacrifice of carrying out this thought.

The short *résumé* which we have endeavored to give could not, of course, touch upon many subjects which were mentioned by Drs. Dettweiler and Penzoldt, who so ably conducted the discussion. We have only tried to lay before you the great features of the position taken by German medical science at

the present time upon so important a matter. If phthisis will be cured in some other way by therapeutics is still a question of the future. It is not yet decided that phthisis cannot be fought by some other more direct treatment, but so much has been undoubtedly been decided by this year's Congress for Internal Medicine: there is no reason for our folding our hands in idleness. With a clear knowledge of the cause of the disease, which we owe to the discovery of Koch, a new impetus has been received by the physicians. What is now within our power has been clearly demonstrated by the discussions of the Congress, and great responsibilities are laid upon us, the accomplishment of which lies with many self-sacrificing workers.

Death has been at work in Berlin among the German medical philosophers with great force this year. In the last few weeks two well-known and learned men have died whose names are not unknown in America. One is Wilhelm Hack, whose theory of the erectile tissue upon the turbinated bones created so much interest some years ago. He died from heart-failure, while riding a velocipede, on the 23d of April. The second is the pathologist, Carl Friedländer, a name connected with many valuable researches, but chiefly with a discovery bearing his name, the pneumococcus. He died at Meran, on the 13th of May, of phthisis.

SANTONIN-POISONING.

To the Editors of the THERAPEUTIC GAZETTE:

GENTLEMEN:—On pages 209-11 of the March number of the GAZETTE is to be found a correspondence from Paris, in which are mentioned some points on "santonin-poisoning" of great benefit to the physician. I have seen nothing on this subject for years, and have often wondered if physicians ever were troubled as I have been with this much-lauded drug, santonin.

If American physicians happen to poison their patients with this drug, they either do not care to publish it, or do not take interest enough in the matter to do so. I have used santonin for seven years in quite a number of cases, and have had some ill luck with it.

The first case of poisoning with it was with one of my own children, a little girl of 6 years. She presented every symptom of worms, and I thought that I would give her santonin. I gave 2-grain doses, morning and night, for two days and nights, taking care to keep the bowels moving every day. On the morning

of the third day I was sent for in haste by my wife, as the child was having convulsions. There had been three convulsions before my arrival, and only one after. My wife had given a large dose of castor oil as soon as the child could swallow it. The bowels moved freely in two or three hours, and the symptoms of convulsions were all over. Sixty odd large worms were expelled within twenty-four hours.
